procedures involving 260 ± 58° of treatment.<sup>28</sup> Posttreatment IOP was reduced to 23.6 ± 11.1 mm Hg from a baseline of 35.1 ± 8.6 mm Hg at mean follow-up of 19 months. Complications included two retinal detachments, one case of hypotony, and one case of decreasing vision from hand motion to no light perception vision. Gayton et al. compared the combined procedures of cataract extraction (CE) and trabeculectomy with CE and ECP.<sup>27</sup> They found that 30% of combined CE–ECP patients achieved an IOP below 19 mm Hg at 2 years of follow-up.<sup>29</sup>

Goniotomy and Trabeculotomy

Sarwat Salim, David S. Walton

10.27

**Definition:** Anterior segment surgical techniques for the treatment of childhood glaucoma.

Key Features

- Angle surgery uses an ab interno or ab externo surgical approach to create a direct communication between the anterior chamber and Schlemm’s canal by incising the trabecular meshwork to lower intraocular pressure.
- Trabeculotomy is performed when the cornea is too cloudy to allow visualization of the angle or when the operating surgeon is unfamiliar with the goniotomy technique.
- Specialized operating instruments: goniotomy uses operating gonioscopy lens and cutting needle or knife; trabeculotomy uses trabeculotomes, Prolene suture, or illuminated microcatheter.
- Success of goniosurgery for primary congenital glaucoma relies on adequate development of the filtration angles based on gonioscopic assessment.

Associated Feature

- Postoperative hyphema is a complication of both procedures.

INTRODUCTION

Goniosurgery represents a unique approach to glaucoma surgery because its goal is to improve outflow facility. By incising the tissue obstructing the trabecular meshwork (Fig. 10.27.1), a direct conduit between the anterior chamber and Schlemm’s canal is created. This is in contradistinction to the creation of an aqueous bypass through a surgical fistula, as seen in filtration surgery. The modern era of goniosurgery began with goniotomy, first performed by Barkan, and has been shown to be effective in the treatment of many types of childhood glaucomas.<sup>1</sup> The growing popularity of trabeculotomy to achieve similar results to goniotomy occurred in parallel

with the introduction and use of the operating room microscope for anterior segment ophthalmic surgery.<sup>2</sup>

INDICATIONS

The indications for goniotomy and trabeculotomy are similar, with trabeculotomy often reserved for cases where adequate visualization of the angle is compromised by corneal opacification. Goniosurgery can be performed in both primary and secondary glaucomas, with variable expected outcomes (Table 10.27.1). The glaucoma type and the severity of the angle defects are the most important prognostic factors when entertaining these interventions, whereas the age of the patient is of less importance.

INSTRUMENTS

Specialized instruments are necessary and must be available for both trabeculotomy and goniotomy procedures. A goniotomy may be performed with use of an independent head-mounted light source and magnification loupe or with a tilting microscope, but a trabeculotomy always requires the surgical microscope. Suggested necessary supplies and instruments are listed in Table 10.27.2.

TABLE 10.27.1 Diagnostic Indications for Goniosurgery

Favorable Prognosis	Unfavorable Prognosis
Infantile primary congenital glaucoma (PCG)	Nevus flammeus–associated glaucoma
Iridotrabeculodysgenesis (iris hypoplasia)	Newborn PCG
Juvenile open-angle glaucoma	Axenfeld–Rieger anomaly/syndrome
Recurrent infantile PCG	Neurofibromatosis (NF-1)
Congenital aniridic glaucoma	Acquired aniridic glaucoma
Congenital infantile rubella glaucoma	Infantile aphakic glaucoma
Corticosteroid-induced glaucoma	Congenital iris ectropion syndrome
Glaucoma secondary to uveitis	Lowe syndrome–related glaucoma

TABLE 10.27.2 Instruments and Supplies: Goniotomy and Trabeculotomy Procedures

Goniotomy	Trabeculotomy
Supplies	
Balanced saline solution (BSS)	BSS
Apraclonidine 0.5%	Apraclonidine 0.5%
Pilocarpine hydrochloride (HCl) 1%	6-0 nylon suture
Intracameral acetylcholine chloride 1:100	9-0 or 10-0 absorbable suture
Viscoelastic material	10-0 nylon suture
9-0 or 10-0 absorbable suture	
70% isopropyl alcohol	
Instruments	
Loupe or tilting operating microscope	Operating microscope
Operating gonioscopy lenses—small and large	Paracentesis knife
Barkan lens; Swan–Jacob lens	Trabeculotomy probes (Harms)—right and left
Goniotomy knives: No. 69 Beaver blade	
Storz SP62233; Swan knife	Vannas scissors
No. 15 Bard–Parker blade	
25-gauge needle	
Locking fixation forceps	
Paracentesis knife	

Fig. 10.27.1 Goniotomy procedure showing incision of the trabecular meshwork.

## PREOPERATIVE CARE

Attention to the preoperative preparation of a patient for a goniotomy or trabeculotomy procedure is helpful. Glaucoma medications used prior to a planned goniotomy can successfully clear a glaucoma-related corneal opacity and improve view of the angle during surgery. Oral acetazolamide, at a dose of 10–15 mg/day, can produce significant lowering of intraocular pressure (IOP) and clearing of the cornea within 1 week. However, this medication should be discontinued after surgery to allow restoration of aqueous production to decrease the risk of postoperative hypotony and a secondary reflux hyphema.

Congenital nasolacrimal duct obstructions and acute respiratory infections are common in infants and young children. If a patient presents with dacryocystitis and purulent discharge, successful lacrimal probing should be performed prior to the planned glaucoma procedure. Upper respiratory infections also must be recognized and may postpone general anesthesia.

## EXAMINATION UNDER ANESTHESIA

Following the induction of anesthesia, the ocular examination is repeated to confirm and obtain additional clinical patient information. Because of the IOP-lowering effect of inhalational anesthetic agents, tonometry is best done soon after the initiation of anesthesia. Corneal diameter measurements and appearance of the optic nerves should be recorded for comparison with future observations. Specialized assessments, including anterior segment slit-lamp examination, gonioscopy, corneal pachymetry, photography, and ultrasonography, can be reserved for this time.

Gonioscopy is essential preparation for goniotomy and trabeculotomy procedures. This is best performed during the examination under anesthesia (EUA) by using Koeppel lenses, which provide a direct view of the filtration angle, or alternatively with mirrored lenses by using the operating microscope. The angle anomaly or acquired defects must be assessed to determine their severity, to establish the diagnosis of the glaucoma type, and to prepare for appropriate surgical procedure. The surgeon's intimate familiarity with the architecture of the angle structures is vital for a successful procedure. When a goniotomy is planned, corneal clarity sufficient to allow visibility of the angle structures must be confirmed at the time of the EUA.

## PROCEDURES

### Goniotomy

The surgical technique for goniotomy has not changed significantly since Barkan's original description, which persists as the best reference for this procedure.<sup>3</sup> If the gonioscopic view is impeded by epithelial edema despite medical management, the epithelium can be removed intraoperatively to provide a clearer window to view the angle adequately. This is usually accomplished by applying a small drop of 70% isopropyl alcohol to the cornea, followed by gentle removal of the epithelium by using a rounded scalpel blade. Before preparation of the surgical field, apraclonidine 0.5% is applied to the limbal region in proximity to the angle quadrant to be treated to reduce the amount of postoperative reflux hyphema. After the eye is prepped and draped in the usual manner, the lashes are taped to prevent contact with the goniotomy instruments. The eye is positioned with the plane of the iris tilted away from the surgeon after placement of locking-fixation forceps on the vertical rectus muscles, if nasal or temporal goniotomy is to be performed (Fig. 10.27.2). Conversely, for an inferior goniotomy, the horizontal rectus muscles can be fixed with forceps. The operating microscope should be tilted toward the surgeon to enable a comfortable view of the angle through an operating goniolens placed on the cornea. The lens must be small enough to allow entry of the operating knife or needle through the peripheral cornea. Rotation of the eye prior to entry will change the position of the incision in the trabecular meshwork, whereas rotation after entry can enable a longer trabecular meshwork incision above and below the starting point. Viscoelastic material may be introduced into the anterior chamber prior to the goniotomy procedure to reduce the risk of losing the anterior chamber. Some surgeons also prefer to use low-strength pilocarpine or miocchol preoperatively to constrict the pupil to lessen the risk of injury to the crystalline lens. However, one needs to be mindful that these agents may lead to narrowing of the angle from forward shift of the lens-iris diaphragm, making the procedure technically more difficult.

The goniotomy needle or knife is inserted into the anterior chamber and its path viewed attentively as it passes across the anterior chamber. The

**Fig. 10.27.2 Goniotomy.** The eye is fixated with forceps and rotated away from the surgeon to facilitate entry of the knife or needle through the peripheral clear cornea.

**Fig. 10.27.3 Goniotomy.** The plane of entry of the cutting instrument is carefully monitored.

cutting instrument should be visually guided across the anterior chamber anterior to the iris (Fig. 10.27.3). The mid-trabecular meshwork is engaged diametrically opposite the point of entry (Fig. 10.27.4), and the incision is then extended to the right maximally. The knife may be returned to the starting point followed by continuation of the trabecular incision to the opposite side. The incision should be created smoothly with minimal resistance and effort while keeping the knife at the same depth into the trabeculum. The progress of the incision in the trabecular meshwork can be followed by visualization of a white line or cleft. Usually 4–6 clock hours of trabecular meshwork is incised. Following careful removal of the knife or needle, the anterior chamber is deepened and the entry site secured, if necessary. Any remaining viscoelastic material must be removed by irrigation. A small reflux hyphema commonly occurs and ceases after restoration of the anterior chamber.

**Fig. 10.27.4 Goniotomy.** The incision in the trabeculum is visualized behind the cutting instrument.

## Trabeculotomy

For trabeculotomy, the eye is prepared and positioned in a manner similar to that for adult eye surgery. A temporal approach may be considered to preserve the superior conjunctiva for future filtration surgery, if ever indicated. A fornix or limbal-based peritomy is performed to expose sclera above Schlemm's canal. An anterior chamber paracentesis is placed for future access to the anterior chamber. A 3-mm triangular partial-thickness scleral flap is created and extended anteriorly to allow visualization of the more anterior darker-blue limbal tissue adjacent to the sclera. A radial scleral incision 2 mm in length is then made over the sclerolimbic junction and continued more deeply until the circumferential fibers of Schlemm's canal are seen and entry occurs, often evident by leakage of clear fluid or blood. The presence and patency of Schlemm's canal may be confirmed by introducing a short segment of 6-0 Prolene or nylon suture material. In some cases, if the view permits, a gonioscope may be used to establish the proper location of the suture in the angle. In cases with cloudy corneas, attention should be directed to the resistance encountered during the passage of the suture, which should enter with minimal difficulty when correctly placed.

Trabeculotomes, right and left, are used to incise the inner wall of Schlemm's canal and the trabecular meshwork. The distal arm of the instrument is entered into Schlemm's canal and advanced for approximately 2 clock hours circumferentially (Fig. 10.27.5). The instrument is then rotated into the anterior chamber without encountering resistance and above the iris to expose approximately two thirds of its length (Fig. 10.27.6). The proximal arm serves as a guide during the procedure. The trabeculotome is then withdrawn and a similar maneuver performed on the opposite side of the scleral incision. It may be helpful to introduce a small amount of viscoelastic before the pass of the trabeculotome to make the eye firm and to move the iris more posteriorly, away from the plane of the trabeculotome, to minimize complications. A small hyphema may occur. The scleral flap is closed with interrupted 10-0 nylon or 8-0 polyglactin sutures. The conjunctiva is repaired with a 9-0 or 10-0 polyglactin suture.

An alternative trabeculotomy technique that allows the trabecular meshwork to be opened 360° employs a 6-0 polypropylene suture that is fed into Schlemm's canal circumferentially before being pulled into the anterior chamber through the trabeculum.<sup>4</sup> This procedure, which has worked well, has no indication different from goniotomy and standard trabeculotomy. Recently, illuminated microcatheter (iTrack 250A; iScience Interventional, Menlo Park, CA), has been employed to perform circumferential trabeculotomy.<sup>5,6</sup> After identification of Schlemm's canal, as in traditional trabeculotomy, the microcatheter is introduced into the canal and threaded circumferentially around the canal. After successful cannulation, both ends of the catheter are grasped, pulled in opposite directions, and removed from the eye, breaking through the trabecular meshwork. The illuminated microcatheter offers the advantages of verification of the catheter tip inside the Schlemm's canal and prevents inadvertent misdirection into the suprachoroidal space that could potentially occur with suture

**Fig. 10.27.5 Trabeculotomy.** Minimal resistance is encountered when the distal arm of the trabeculotome is placed in Schlemm's canal.

trabeculotomy. In addition, unlike traditional trabeculotomy performed with trabeculotomes, this technique may allow treatment of the entire angle in one setting, minimizing surgical and anesthetic risks.

Viscotrabeculotomy is another technique that involves injection of high-viscosity sodium hyaluronate (Healon GV, Pfizer, NY) into Schlemm's canal prior to the passage of trabeculotome.<sup>7</sup> The viscoelastic agent prevents collapse of Schlemm's canal, adhesions of incision lips, and shallow anterior chamber.

Grover et al.<sup>8</sup> recently described a new technique for ab interno trabeculotomy. This procedure is termed *gonioscopy-assisted transluminal trabeculotomy* (GATT). Essentially, paracentesis are made in the superonasal or inferonasal quadrant and temporally using a 23-gauge needle. A viscoelastic agent is injected into the anterior chamber. Under gonioscopy visualization, a 1- to 2-mm nasal goniotomy is created. Microsurgical forceps are used to direct a suture or illuminated microcatheter into Schlemm's canal. The distal tip of the suture/catheter, once it has passed through the entire canal, is retrieved and externalized, thus creating a 360° trabeculotomy. The viscoelastic is removed from the anterior chamber with stromal hydration of the paracentesis sites.

## POSTOPERATIVE CARE

An eye patch and shield are applied after the surgery and removed at the first examination. A combination of corticosteroid and antibiotic drops is prescribed for a few days. The risk of an excessive postoperative hyphema may be reduced by administration of topical apraclonidine 0.5% and head elevation. Frequent follow-up examinations are necessary to determine the success or occurrence of complications.

## RESULTS

The results of goniotomy and trabeculotomy vary greatly with the type of glaucoma and severity of the filtration angle defects. The procedures are considered to have similar efficacy for childhood glaucomas, and unfortunately, there is no reason to consider either after failure of the other.

The outcome of goniotomy for primary congenital glaucoma is very favorable, with a reported success rate greater than 80%.<sup>9</sup> As should be expected, children with newborn primary congenital glaucoma respond poorly to goniosurgery related to their severe filtration angle anomaly.<sup>10</sup> The success of goniotomy for primary congenital glaucoma has been correlated inversely with the severity of the IOP and secondary abnormalities.<sup>11</sup> Relapse

**Fig. 10.27.6 Trabeculotomy.** (A,B) The trabeculotome is rotated inwardly and parallel to the iris to lessen the risk of injury to the cornea and the iris.

following successful goniotomy is not common, and more common after repeat procedures.<sup>12</sup> For children with primary infantile glaucoma, repeat goniotomy should be offered for relapse before other procedures are recommended on the basis of gonioscopic determination of the potential for additional incision of the trabeculum.

The results of goniotomy for other types of childhood glaucomas are quite variable (see Table 10.27.1). The results are disappointing often with glaucoma related to Sturge–Weber syndrome or aphakia. In contrast, select patients with uveitic glaucoma have obtained excellent results.<sup>13</sup>

Trabeculotomy is just as effective in cases of primary congenital glaucoma. A study of trabeculotomy for 99 eyes reported success rates of 92% and 82% at 5 and 10 years, respectively, after one or multiple procedures.<sup>14</sup> Yassin et al.<sup>15</sup> reported surgical outcomes of trabeculotomy, trabeculectomy, and combined trabeculotomy-trabeculectomy in 148 eyes with primary congenital glaucoma over a 20-year period. All procedures resulted in a progressive decline in surgical success (defined as IOP  $\leq$  21 mm Hg with

or without medications) from 97% at 5 months to less than 50% after 11 years, without statistically significant difference between procedures. Khalil et al.<sup>16</sup> compared the outcomes of primary trabeculotomy to combined trabeculotomy-trabeculectomy in eyes with congenital glaucoma and reported a success rate of 85.7% in both groups at 3 years. Given similar outcomes with both procedures, the authors suggested that trabeculotomy should be the initial surgery for congenital glaucoma. Ozawa et al.<sup>17</sup> reported higher success rates in primary childhood glaucoma than in secondary childhood glaucoma after conventional trabeculotomy.

Beck et al.<sup>18</sup> evaluated surgical outcomes of 360° suture trabeculotomy in primary congenital glaucoma with a poor prognosis (birth-onset presentation, presentation after 1 year of age, prior failed goniotomy, glaucoma after cataract surgery, and glaucoma associated with other ocular and systemic anomalies) and concluded that this technique has a role in children who have a wide range of ocular pathologies and historically have been thought to be poor candidates for traditional angle surgery. They reported success rates of 63% and 58% at 1 and 2 years, respectively.

El-Sheikha et al.<sup>7</sup> compared the efficacy of with that of conventional trabeculotomy in a prospective, randomized comparative study. Both techniques were reported to have similar IOP reduction with no additional benefit with viscotrabeculotomy. The major limitation of this study was a very short follow-up of 6 months.

Girkin et al.<sup>6</sup> found qualified success of 91.6% and unqualified success of 83.3%. Approximately 50% of the eyes had 360° of the angle treated successfully, with a mean IOP reduction of 57%. The most common complication reported was transient hyphema. In other work, at 2 years postoperatively, microcatheter trabeculotomy demonstrated lower IOP and less need for subsequent glaucoma procedures compared with conventional trabeculotomy.<sup>19</sup>

Grover et al.<sup>20</sup> reported outcomes of GATT in 14 eyes with primary congenital glaucoma and juvenile open-angle glaucoma at a mean follow-up of 20 months. The mean IOP decreased from 27.3 mm Hg to 14.8 mm Hg, and the mean number of medications required decreased from 2.6–0.86. The most common postoperative complication was hyphema, which cleared by 1 month in all cases. GATT may be superior to goniotomy because it opens 360° of the angle unlike goniotomy. The ab interno approach also spares the conjunctiva for future filtration or drainage implant surgery.

## COMPLICATIONS

Serious surgical complications after goniotomy and trabeculotomy are infrequent. Postoperative hyphemas are commonly seen after both procedures but usually are of no clinical significance. When a significant amount of blood does reflux into the anterior chamber and causes a secondary elevation of the IOP, anterior chamber washout must be considered. Infection has rarely been reported after goniosurgery. Injury to the iris or lens is potentially possible with both procedures. Iridodialysis and Descemet's membrane detachment of the cornea can occur with false entry of the trabeculotome during trabeculotomy. As mentioned before, one potential complication of suture trabeculotomy is misdirected suture into the suprachoroidal space. With circumferential trabeculotomy using illuminated microcatheter, 360° passage of the catheter may not be achievable, especially in eyes with previous angle surgery. Most complications of goniosurgery can be circumvented by careful selection of cases and appropriate preoperative preparation, familiarity with the anterior segment and angle structures, and meticulous surgical technique.<sup>21</sup>

available online at  
[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** Minimally invasive glaucoma surgery and microincisional glaucoma surgery offer the theoretical advantages of lowering intraocular pressure with incisional surgery but have lower risks compared with conventional operations. Approaches include the use of microdevices for removal or bypass of abnormally high-resistance tissues.

## Key Features

- Minimally invasive glaucoma surgery offers lower surgical and postoperative risk, but often less IOP reduction, compared with conventional glaucoma surgical techniques.
- Minimally invasive and microincisional glaucoma surgeries:
  - Trabeculectomy ab interno (trabectome).
  - Trabecular meshwork bypass stents.
  - iStent G1 and iStent G2 Inject.
  - Hydrus.
  - Subconjunctival shunt.
  - Suprachoroidal shunts.
  - Gold shunt.
  - CyPass.
  - iStent G3 Supra.
  - Canaloplasty.
  - Endocyclophotocoagulation.

## INTRODUCTION

Progress in biomedical engineering and the ability to image and understand delicate outflow structures in the living human eye using optical coherence tomography<sup>1</sup> have led to the development of new surgical options for glaucoma. Glaucoma is now a leading cause of irreversible blindness with increasing prevalence in an aging population.<sup>2,3</sup> Despite the many new arrivals (see list below), the concepts behind trabeculectomy are not entirely new:

- Ab interno (trabectome; Neomedix, Tustin, CA).<sup>4</sup>
- Trabecular meshwork (TM) bypass stents (iStent G1 and iStent G2 Inject; Glaukos, Laguna Hills, CA).<sup>5</sup>
- Hydrus (Ivantis, Irvine, CA).<sup>6</sup>
- Subconjunctival (XEN; AqueSys, Irvine, CA); or suprachoroidal shunts (Solx, Waltham, MA).<sup>7</sup>
- Cypass (Transcend Medical, Menlo Park, CA).<sup>8</sup>
- iStent G3 Supra, Glaukos, Laguna Hills, CA), canaloplasty (iScience Interventional, Menlo Park, CA).<sup>9</sup>
- Endocyclophotocoagulation (Endo Optiks, Little Silver, NJ).<sup>10</sup>

Open-angle glaucoma has been surgically treated for 150 years by either increasing external filtration (De Wecker, 1867),<sup>11,12</sup> internal filtration (angle surgery: Taylor, 1891<sup>13</sup>; suprachoroidal drainage: Heine, 1900<sup>13</sup>), or ciliodestruction (Hancock, 1861).<sup>13</sup>

The development of new devices and technologies was spurred by the realization that the standard surgeries performed today for

glaucoma—trabeculectomy and epibulbar glaucoma drainage device surgery—have relatively high failure and complication rates.<sup>14</sup> Although not as rudimentary and unsuccessful as at the time of their inception in the form of guarded external filtration by Sugar in 1962<sup>15</sup> or in the form of the gold wire shunt by De Wecker in 1876,<sup>11</sup> both present iterations, trabeculectomy and epibulbar glaucoma drainage device (“tube shunt”) implantation, seem suboptimal, given that postoperative interventions may have to be performed in 70% of trabeculectomies and 25% of tube shunts.<sup>16</sup> In the “tube versus trab” (TVT) study, early postoperative complications occurred in 37% of patients with trabeculectomy and 21% of patients with tube shunts, whereas additional complications during 5 years of follow-up occurred in 38% of trabeculectomies and 36% of tube shunts, and at least two lines of vision were lost in 43% of trabeculectomies and 46% of tubes.<sup>16</sup> For the past 30 years, trabeculectomy was the standard of care for surgical intervention for glaucoma and was made more successful by refinements, such as the use of antimetabolites, argon laser suture lysis, and releasable sutures, but this has also led to more complications, for example, hypotony with or without maculopathy, shallowing of the anterior chamber, choroidal effusions or hemorrhages, hyphema, and cataract formation. Long-term complications are associated with undesirable bleb morphology resulting in late bleb leak, blebitis, or endophthalmitis.<sup>17–22</sup>

As found in the TVT,<sup>23</sup> tube shunts and trabeculectomies can achieve low postoperative intraocular pressure (IOP)—tube shunts averaged 14.4 mm Hg and trabeculectomies achieved 12.6 mm Hg (but were not significantly different from each other) after 5 years.<sup>14</sup> Because these surgeries have not been compared in a randomized controlled fashion to microincisional glaucoma surgery (MIGS), it is not known whether pressure lowering is superior and worth the considerable risk. In fact, prospectively collected MIGS data indicate only slightly higher IOP of 15.2 mm Hg for phaco-trabectome procedures at 5 years<sup>24</sup> and 16.1 mm Hg for the iStent with same session phacoemulsification (“phaco”) at 5 years.<sup>25</sup> The most serious complication of MIGS is a temporary, greater than 10 mm Hg IOP increase during the early postoperative phase that can occur in 3%–10% of trabectome patients<sup>26</sup> and nearly 10% of iStent patients.<sup>27</sup> Early postoperative, transient hyphema is characteristic for all canal surgeries and more common in procedures that generate access to many outflow segments by bypassing the TM over a large arc of the naturally discontinuous and septated Schlemm’s canal (SC). Two reasons why the ab interno procedures are done on the nasal TM are the ease of surgical access directly opposite the surgeon and Schlemm’s canal being shown to be 33% wider nasally than temporally,<sup>28</sup> potentially offering greater outflow.

This chapter reviews presently available minimally invasive glaucoma surgery and MIGS ordered by their extent of outflow tract alteration, mechanism, and degree of invasiveness. MIGS bypasses the primary outflow resistance in glaucoma that resides in the TM (reviewed in<sup>29</sup> and<sup>30</sup>), whereas suprachoroidal shunts enhance uveoscleral flow, and others (e.g., XEN) involve alternative drainage pathways entirely.

## CONSIDERATIONS FOR PATIENT SELECTION

Generally, minimally invasive glaucoma surgery and MIGS can be considered in any patient who is a candidate for trabeculectomy or tube shunt implantation. With their improved safety profile, these procedures may also be performed before someone qualifies for conventional filtering surgery. Another argument for earlier surgical intervention are results

**Fig. 10.28.1** Modified Swan–Jacob gonioscope for right-hand dominant (A) and left-hand dominant surgeons (B) that is commonly used in microincisional glaucoma surgery (MIGS). (Courtesy Neomedix Corp.)

from the Collaborative Initial Glaucoma Treatment Study, which suggested that mild to moderate glaucomatous optic neuropathy may be controlled with IOPs in the high teens, whereas advanced changes required IOPs in the low teens.<sup>31</sup> Compliance even with modern once-a-day prostanoids may be as low as 30% at 1 year,<sup>32</sup> and only 10% of patients have their medication available continuously.<sup>33</sup> The cost of surgical reduction of IOP decreases with time because the cost of surgery is divided by the number of years of life from the time of surgery. This is in contrast to medical therapy, which escalates with time paralleling the increased cost and number of medications required to control IOP.<sup>34</sup> When nonmedical therapy is chosen as the first line of glaucoma treatment, the costs of glaucoma, up to \$150 000 per quality-adjusted life-year can be greatly reduced and even provide returns for the healthcare spending.<sup>35</sup> Furthermore, increased diurnal variations of IOP in glaucoma are an independent risk factor for progression,<sup>36,37</sup> and IOP may be better controlled surgically than medically.<sup>34,38,39</sup>

Further considerations for MIGS are patients with poor conjunctiva, patients at risk for postoperative hypotony (i.e., younger age, male gender, moderate to high myopia)<sup>40</sup> or for the development of a serous or hemorrhagic choroidal effusion (myopia, older age, hypertension, atherosclerosis, history of a choroidal effusion or hemorrhage, short axial length—especially nanophthalmos and previous vitrectomy<sup>41–43</sup>). Expedited visual recovery compared with that in trabeculectomy is an additional benefit, especially for monocular patients. Ab interno procedures may produce transient visual obscuration from hyphema, which varies, depending on the extent of access to the angle and the subsequent potential for pressure gradient and flow reversal.<sup>44</sup> As most MIGS procedures are performed under gonioscopic visualization, patients must have clear corneas and a sufficiently wide lid fissure (Fig. 10.28.1). Surgeons have to master gonioscopy and learn to control movements in a highly confined and vulnerable space as

well as instrument rotation using only one hand, as when the direction of ablation is changed in trabectome surgery.

## ANGLE SURGERIES

### Trabecular Microbypass Stents

#### Concept

These stenting devices (Fig. 10.28.2) are inserted internally to offer a wider pore into Schlemm's canal because 50% of the pores on the inner wall of Schlemm's canal had a diameter 1  $\mu$ m or less in one histological study.<sup>45</sup> Trabecular microbypass stents directly connect the anterior chamber to SC and the collector channels after implantation. The advantages of having a trabeculotomy-maintaining device currently seem to exceed the disadvantages of a permanent foreign body in the eye that could migrate or damage adjacent structures. The recently introduced iStent G2 Inject will be discussed before the original trabecular microbypass stent, the iStent G1, because we have ordered the discussion of angle surgeries according to their degrees of invasiveness and size.

#### iStent G2 Inject (GTS-400)

The preoperative and anesthetic regimens are identical to those of standard phaco.<sup>46</sup> After cataract extraction, intracameral acetylcholine is used to induce miosis. The chamber is deepened with viscoelastic. The insertion device is moved across the chamber under gonioscopic view by using a Swan–Jacob gonioscope. The second-generation iStent, iStent Inject (Glaukos Corporation, Laguna Hills, CA), is 0.4 mm long and 0.3 mm wide and is made of titanium with a heparin coating. Compared with the larger iStent G1 discussed below, it contains two preloaded stents to avoid

**Fig. 10.28.3** Trabecular microbypass stent iStent G1. (A) Magnified view of 1 mm titanium stent (*insert: size comparison with intraocular lens*). (B) Preloaded in inserter. (C) Implanted in Schlemm's canal. (Courtesy Glaukos Corp.)

having to withdraw and reload the inserter, thereby avoiding hypotony and reflux of blood from the collector channels and SC.<sup>47</sup>

### Technique

The bullet-shaped stents are placed by direct forward penetration into the canal rather than the sideward, sweeping implantation of the first-generation device.<sup>5</sup> Because it is not angled, there is a single stent design for either the right or the left eye. Stents can be placed approximately 2 clock hours apart.<sup>48</sup>

### Results

Bahler et al. found that the outflow facility doubled after inserting one stent and doubled again after the second stent in an anterior chamber perfusion model.<sup>47</sup> Although insertion was done under ideal viewing conditions with direct visualization through a microscope and not gonioscopically through a cornea, the inevitable stent tilt caused apposition of some of the drainage holes against SC or the TM as demonstrated with electron microscopy. The reported data, to date, suggest that from a mean baseline IOP of 22 mm Hg, two iStent G2s lowered IOP by 30% to 15 mm Hg, on average.<sup>27,49–51</sup> The only identified risk factor for failure is lower baseline IOP.<sup>49</sup> The most common complications are hyphema/reflux from deroofing a vein in up to 90%<sup>50</sup> and transient elevations in IOP in 10–15%.<sup>27,52</sup> In the largest study (n = 99), 7% of stents were obstructed, although only half of those needed to be treated (laser synechiolysis).<sup>27</sup>

### iStent G1

The original iStent G1 (Glaukos Corporation, Laguna Hills, CA, USA) (Fig. 10.28.3) is nearly three times as large as the iStent G2 Inject. It has a 1-mm-long body with an angled intake and is also coated with heparin. The body of this titanium device is inserted through the nasal TM into SC by using a dedicated injector. Because SC is discontinuous and septated,<sup>1,28</sup> outflow segments can likely be accessed over 30–60° with a single device.<sup>53</sup>

### Technique

Directing the tip of the implant toward the TM and SC, the stent is inserted midnasally (Video 10.28.1). Tilting the stent 15° toward the TM may ease insertion.<sup>54</sup> Intraoperative confirmation of placement into SC is achieved by noting blood reflux through the stent. The stent is then released from the applicator and the applicator withdrawn from the eye. Tapping the stent can help confirm that it is parallel to the iris and fully inserted. Multiple stents can be placed approximately 2 clock hours apart facing opposite directions.<sup>48</sup> The viscoelastic is aspirated and the wound hydrated. Postoperatively, a fourth-generation fluoroquinolone is given four times per day for 1 week, and prednisolone acetate 1% 4–6 times a day (tapered weekly). All oral or topical glaucoma medications are discontinued and added back, as needed. Proper placement can be confirmed by using ultrasound biomicroscopy (UBM).

### Results

Measurements on human donor eyes have shown that insertion of one stent can nearly double the outflow facility<sup>55</sup> and that the insertion of

two stents can more than quadruple it.<sup>47</sup> The strongest level of evidence comes from a randomized, parallel trial (n = 36) that compared patients who underwent stand-alone phaco with a combined group of patients who underwent phaco with stent placement.<sup>56</sup> After 15 months, there was a 17% decrease in IOP in the combined group compared with only a 9% decrease in the stand alone phaco group despite being on one more medication, on average. The only study-related complications were two cases of stent malposition. Another, larger randomized, parallel trial (n = 240) required an entry IOP at 22 mm Hg or greater following medication washout.<sup>5</sup> By protocol, postoperative IOP was maintained below 21 mm Hg with topical medications in both groups, so mean reduction of IOP versus baseline was only 1.5 mm Hg in the treatment group versus 1 mm Hg in the control group. In the combined group, 66% achieved a 20% reduction in IOP without medications, but it was only 48% in the phaco group. After 24 months, the IOP decrease from baseline was 8% in the combined group versus 1% in the phaco group.<sup>57</sup>

On average, from a mean baseline IOP of 19–21 mm Hg, one first-generation iStent lowers IOP by 21%, two by 23%, and three by 31%.<sup>50</sup> A meta-analysis found that standalone iStent (without phaco) with one iStent lowered IOP by an average of 22% after 18 months, two iStents by 30% at 6 months, and three iStents by 41% after 6 months.<sup>58</sup> Medication load was reduced by one medication in all three groups. For combined iStent with phaco, a meta-analysis found that one iStent lowered IOP by an average of 26% after 18 months, two iStents by 18% after 6 months, and three iStents by 20% after 6 months, again on one less medication compared with baseline.<sup>59</sup> Averaging of present data suggests that the insertion of either two first-generation iStents, three first-generation iStents, or two second-generation iStents can help achieve an IOP 15 mm Hg or less off medications in approximately 84 ± 6% of cases for the first 1–1.5 years, with results of single first-generation stents being more variable.<sup>49,60,61</sup>

The complication profile is similar for first- and second-generation iStents. Complications in first-generation studies similarly include obstruction by fibrin or peripheral anterior synechiae (PAS) (as occurred in 4% of 111 patients<sup>5</sup>) and stent malposition (14%). Stent obstruction has been managed with observation, argon laser, and injection of tissue plasminogen inhibitor (this last intervention was not successful). Four of 111 patients were taken back to the operating room to reposition or replace the stent. Although increased IOP following stent placement can be relatively common (IOP spike >5 mm Hg in 20% of 96 cases),<sup>62</sup> it occurred more frequently in the control group (stand-alone phaco) in the largest trial.<sup>57</sup> Loss of two lines of Snellen visual acuity has not been attributed to the stent in any case. There are no reports of choroidal effusion, persistent hypotony, bleb formation, or endophthalmitis after stent placement. Experimental outflow studies in animal models suggest that outflow is restricted to the area of implantation.<sup>63</sup>

## Hydrus: Ab Interno Schlemm's Canal Scaffold

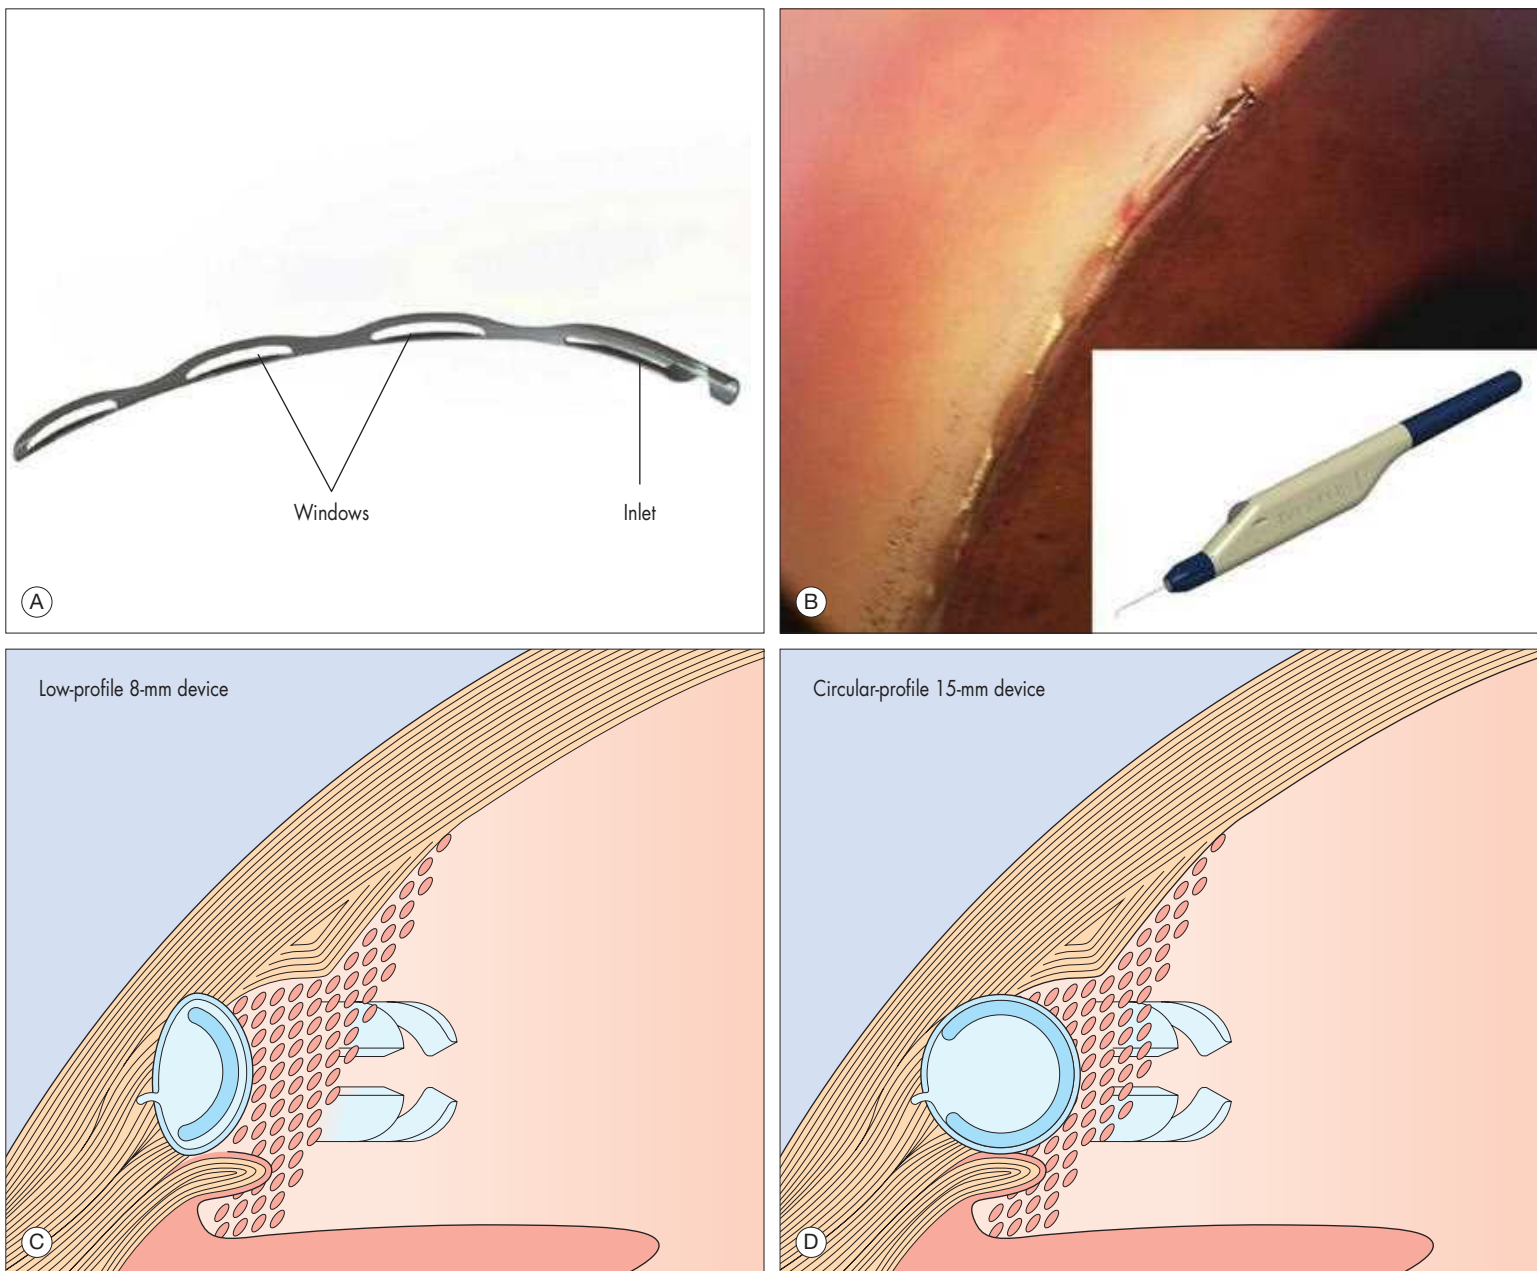

### Concept

This scaffold device is composed of nitinol, a nickel–titanium alloy that forms a flexible, open stent. There is a 1-mm terminal lumen that is left in

See clip:  
10.28.1

**Fig. 10.28.4** Ab interno Schlemm's canal scaffold Hydrus. (A) Magnified view showing the inlet which is left in the anterior chamber. (B) Gonioscopic view of the implant (insert: device inserter). Comparison of low-profile 8-mm device (C) and 15-mm device (D). (Courtesy Ivantis Inc.)

the anterior chamber as a snorkel. After placement of the initial, 15-mm-long<sup>6</sup> Hydrus microstent scaffold (Ivantis Inc., Irvine, CA), a shorter, flatter, 8-mm-long<sup>64</sup> scaffold was introduced (Fig. 10.28.4), and most reports focused on the second model. The stent functions by dilating SC to a diameter of 241 microns, or approximately four times the physiological cross-section.<sup>6</sup> Besides improving aqueous access to the collector channels by dilating the canal and preventing the TM from prolapsing into SC, the 1-mm snorkel in the anterior chamber allows the TM to be bypassed. Finally, it may also extend the range of circumferential flow by disrupting SC septations, which could otherwise limit flow to only a few clock hours.<sup>65</sup> The 15-mm stent dilates about 5 clock hours of SC and doubles the outflow facility, but the shorter and less curved 8-mm stent was also found to produce similar increases in outflow facility.<sup>6,64</sup>

### Technique

Similar to the iStent, this device is preloaded in an injector to allow insertion into SC under gonioscopic view. After topical and intracameral anesthesia, miosis is induced, and the injector tip is directed along the nasal TM. The hydrus is advanced and engages the TM. After careful insertion, the device is advanced along SC. Following retraction, blood can be seen refluxing from the tip. Viscoelastic is evacuated and the corneal incision closed.

### Results

The single clinical peer-reviewed study performed so far was a randomized, parallel trial comparing IOP reduction with combined phaco with scaffold insertion ( $n = 50$ ) to stand-alone phaco ( $n = 50$ ) for cases of primary open-angle glaucoma (POAG), pseudo-exfoliation, or pigmentary glaucoma.<sup>66</sup> From a mean baseline IOP of 19 mm Hg in both groups on two medications, at 24 months, IOP had decreased to around 16.4 mm Hg (13% decrease) on 1.5 fewer medications with the scaffold versus 17.1 mm Hg (8% decrease) with one less medication after phaco. Although 73% of combined patients were off medications at the end of the study, only 38% of patients who underwent phaco were medication-free. As with most devices, there can be an early but transient IOP spike (defined in this study as an IOP  $>35$  mm Hg) in 26% of combined cases versus 10% of phaco. Focal PAS developed in 19% after 2 years, but as with microbypass stents, the clinical significance is unknown because the cases with or without PAS had a statistically similar IOP and medication load. No patient lost vision.

### Laser-Assisted Endoscopic Trabeculotomy

#### Concept

Laser-assisted endoscopic trabeculotomy (Fig. 10.28.5) can create an immediate bypass of the TM by directing flow into an alternative drainage

**Fig. 10.28.5** Endoscopic laser trabeculotomy. (A) Demonstration of position and size of the probe on an anterior segment slide. (B) View through a microscope. (C) Endoscopic view of chamber angle (top). Hypotony is induced to induce reflux of blood into Schlemm's canal to visualize the ablation target in the setting of poor pigmentation. The probe is held directly against the trabecular meshwork (TM) to apply laser and then moved away to confirm penetration as evidenced by reflux of blood into the anterior chamber. (D) Left: Histology section of circular ablation site. Lips do not roll up against the outer wall as in goniotomy because the surrounding TM is intact and away from the outer wall. Right: Nontreated control. (Courtesy Jens Funk.)

pathway and does not leave behind any stents or devices that may erode, incite a foreign body reaction, or contribute to fibrosis. However, TM ablation has to be large enough and with minimal collateral tissue damage as to not cause a wound-healing response that would cause the ablation sites to close. Krasnow first attempted laser ablation and perforation of trabecular tissue in 1972 with a ruby laser system,<sup>67-71</sup> erbium:yttrium-aluminum-garnet (Er:YAG)<sup>72-74</sup> and excimer laser.<sup>75</sup> Focal Er:YAG trabeculotomy limited to a few microns diameter had been performed soon after the introduction of this laser for capsulotomy and iridectomy, but the effect only lasted several weeks before the trabeculotomies closed.<sup>68,76,77</sup> Dietlein et al. recognized that sufficiently large ablation could only be achieved with end-firing endo-probes that have a 200–320-micron diameter to create large circular craters using 4–6 mJ energy.<sup>78</sup> Despite such extensive ablation, a closure can still occur either via migration of immediately adjacent cell types<sup>79</sup> but also that of remote cell types.<sup>80</sup> The results indicate considerable differences in repair and cell migration mechanisms when the TM is ablated with laser and possibly with other techniques (e.g., trabectome, as discussed below) that occur depending on age and species.

As with endoscopic excimer laser trabeculotomy described above, endoscopic Er:YAG laser (Sklerotom 2.9, Endognost system; Schwind) at a wavelength of 2.94 microns has also been used to increase conventional outflow through 300-micron perforations in the TM.<sup>81</sup> Also in common with an endoscopic excimer laser, because the technique relies on water vaporization, the laser tip must be brought to the TM to avoid excess energy loss to the aqueous humor. A standard treatment of 18 pulses at 16 mJ is typically applied to the nasal TM.

Another challenge common to all ab interno canal procedures is the difficulty in identifying the TM and SC and applying the ablation energy, whether laser or plasma ablation (trabectome) to the correct structure. The laser endoscope probe does not directly enter SC as do ab interno stents (e.g., iStent and Hydrus) and ablation devices (trabectome) so determining the proper placement of subsequent applications are less definite resulting either in incomplete ablation or damage of adjacent tissue. For instance, once SC is entered with the trabectome, ablation continues along the same structure that is easily recognizable by the pale appearance of the outer wall and reflux when pressure is lowered. Because of this, some investigators have developed an ab intracanalicular ablation of TM that guarantees proper anatomical location, the closest approximation to the TM and complete and powerful penetration without damaging other canal structures as the beam is directed inward, toward the center of the anterior chamber.<sup>82</sup>

### Endoscopic Excimer Laser Trabeculotomy Technique

Endoscopic excimer laser trabeculotomy (ELT)<sup>83,84</sup> (AIDA; TUI-Laser, Munich, Germany) increases conventional outflow. The 308-nm wavelength ELT creates 500-micron penetrations through the TM opening into SC.<sup>85</sup> The collateral thermal damage is less than with Er:YAG laser, but

variable energy transmission presents a challenge. Similar to the other procedures described in this chapter, the instrument tip must be inserted across the anterior chamber and guided gonioscopically to the TM. The mechanism of photoablation with this laser is water vaporization with tissue disruption. During the application, the TM blanches, and a few bubbles are seen. Successful penetration into SC produces blood reflux when IOP is less than episcleral venous pressure.

### Results

After a standard application of eight laser shots, 21 patients demonstrated a 32% IOP decrease from a baseline of 25 mm Hg after an average of 2 years while decreasing the mean number of medications from 2.2–0.7. Only 38% of patients sustained a 20% decrease in IOP. A larger group of 75 patients showed a 30% decrease from a baseline of 24 mm Hg after 1 year.<sup>84</sup> However, the number of medications did not change. Only 46% of patients successfully maintained a 20% IOP decrease and had a final IOP less than 21 mm Hg. When combined with cataract surgery, the success rate using the same definition increased to 66%, although the number of medications did not decrease. ELT was compared with 180° selective laser trabeculoplasty (SLT) treatment in a randomized, parallel trial.<sup>83</sup> ELT lowered the IOP by 30% versus 21% in the SLT group. The SLT group had a longer survival time, although the difference was not statistically significant. There was an IOP spike on postoperative day 1 in 20% of the ELT group versus 13% in the SLT group. No vision-threatening complications were reported.

## Trabeculectomy Ab Interno: Trabectome

### Concept

Ab interno trabeculectomy (Fig. 10.28.6) with the trabectome (Neomedix Corp., Tustin, CA) is a plasma surgery technique that uses a bipolar 550-kHz electrode tip to ablate the TM. The device is the result of research funded by the National Institutes of Health (R44-EY015037; Small Business Innovation Research [SBIR]). This device was described 15 years ago by Baerveldt and Chuck,<sup>86</sup> and approved by the US Food and Drug Administration on February 9, 2004, for the treatment of adult and pediatric glaucoma.<sup>87</sup> It represents the refinement of a mechanical goniotomy instrument.<sup>86</sup> In contrast to the TM-bypass surgeries discussed above, this technique removes the substrate of the primary outflow resistance, the juxtacanalicular TM,<sup>88,89</sup> and allows additional access to the outflow system distal to the left and right end of the ablation arc.

As in earlier studies,<sup>26,90</sup> novice surgeons can often only ablate 30–60° of the TM, but because the aqueous flow is not circumferential and SC discontinuous or septated,<sup>65,91,92</sup> aiming for extensive ablation of TM over 180° provides access to more outflow sectors than can be achieved with microstents or scaffolds. This may increase surgical success and broaden indication criteria, including glaucoma types and disease stages previously

**Fig. 10.28.6** Trabectome. (A) Trabectome handpiece with cautery unit. (B) Schematic of trabectome ablating trabecular meshwork (TM), opening a view to the white inner wall of Schlemm's canal. (C) Scanning electron microscopy image of Schlemm's canal after successful TM ablation, with a collector channel seen clearly at the far right.

thought to be contraindicated (e.g., end-stage glaucoma, acute and chronic angle closure, inactive neovascular glaucoma). No foreign body remains in the eye to incite a potential foreign body reaction or device migration. Stents have a considerable risk to be occluded by peripheral anterior synechiae because they provide only a single point of access to SC with relatively high flow speeds. In contrast, 5–6 collector orifices are opened per millimeter of SC following trabectome surgery and at different levels (hidden collector intakes in Fig. 10.28.6), each of which has lower flow speeds and aspiration risk than a single intake. This broad-based access to the outflow system may also explain the slightly higher rate of small hyphemas at the conclusion of the surgery compared with microstents when the IOP may temporarily be lower than the episcleral venous pressure.

Trabectome ablation of TM is fundamentally different from goniotomy in that only minimal TM stumps are left that are unable to occlude the collector channel intakes. Goniotomy is effective in children<sup>93</sup> because the scleral spur is elastic enough to drop posteriorly after the incision, but in adults, the spur is more rigid and allows the TM lips to reapproximate and occlude. It is possible that a short stump of viable TM after trabectome surgery may be advantageous by serving as a viable cell barrier to endothelial cell down growth and descemetization of the angle<sup>70</sup> by maintaining contact inhibition of cell division.<sup>94</sup>

### Technique

Trabectome surgery can achieve high rates of surgical success even in complex glaucomas when the following key steps are followed: (1) Visualization is maximized using an iris-planar, flared incision and avoiding viscoelastics during ablation; (2) outward push during ablation is avoided to prevent damage to collector channel intakes; (3) ablation arc is maximized to access more outflow segments; (4) and hyphema is minimized by pressurizing the anterior chamber with viscoelastic during and at conclusion of surgery (Fig. 10.28.7).

Before combined phaco-trabectome procedures, dilation as for routine phaco is performed with 2.5% phenylephrine and 1% tropicamide. After intracameral preservative-free lidocaine is injected through a paracentesis, a 1.6-mm iris-parallel, uniplanar main incision is fashioned 2 mm anterior to the limbus to improve handpiece mobility (Fig. 10.28.7). The internal, lateral aspects of the incision should be flared to further improve range and eliminate striae from torque. The eye should now be slightly hypotonous to allow reflux of blood into SC, marking the intended ablation site. Wrong site ablation is a common mistake in eyes with lightly pigmented TM because either the ciliary body band or Sampaolesi's line can

**Fig. 10.28.7** Main incision for trabectome surgery into the anterior chamber. Entry is made 2 mm anterior to limbus and parallel to the iris at (1). The left (2) and right (3) internal aspects of the wound are then enlarged, allowing for more torque without striae.

be confused with it. The patient's head is turned approximately 30° away from the surgeon to maximize view of the angle, while the microscope's viewing axis is tilted about 45° toward the surgeon. For patients who may have significant difficulty rotating the neck, the microscope tilt can be increased.

**Fig. 10.28.8** The trabectome tip should be angled 45° and inserted directly anterior to the scleral spur to avoid collapse of the canal. (Adapted from Alward WLM. Color atlas of gonioscopy. Mosby-Verlag, Iowa; 1994. p. 52–7.)

**Fig. 10.28.9** It is more efficient to engage the trabecular meshwork (TM) at a more pointed angle, as in the left inset compared with that in the right inset, where the tip is shown parallel to the TM.

A modified Swan–Jacobs direct gonioscopy lens (Ocular Instruments, Bellingham, WA) is placed lightly on the cornea to confirm angle visualization. The irrigation bottle should be raised to the maximum height and left on continuous irrigation to deepen the angle. By not using any viscoelastic prior or during ablation, optical interfaces and trapping of ablation bubbles can be avoided. Under gonioscopic view, the TM should be approached with the tip at a 45° upward left angle at the level of the scleral spur for right handed surgeons (Fig. 10.28.8). The scleral spur maintains the space and makes it easier for the footplate to glide into SC. Once engaged, exerting slight inward pull helps counteract the natural tendency to push outward, which would force the trabectome handpiece against the outer wall of SC and potentially damage the 50-μm collector channel intakes. It is easier to enter SC slightly toward the left of the opposite side of the anterior chamber because of a more pointed contact (Fig. 10.28.9).

The footplate of the trabectome tip will appear obscured by the transparent, lacy TM when properly inserted. The ablation can be carried out starting at 0.8 mW and titrated up. Blackening along the ablation lips indicates coagulative heat damage that may incite undesirable wound healing and progressive failure. Adequate ablation is confirmed visually by the appearance of the white outer wall SC. Ablation should continue for 90°, the tip is disengaged from SC, rotated 180°, and then inserted where the original ablation was started. The handpiece is rotated and the wrist is pronated such that the ablation can proceed for the remaining

90°. The ablation arc can be maximized with proper goniolens placement, rotation, finger position, and wrist supination and pronation (Fig. 10.28.10). The handpiece is disengaged from the TM and then withdrawn from the eye. A small amount of viscoelastic can be retained to prevent postoperative hypotony and protect against hyphema. Hypotony is very common after standard cataract surgery and can contribute to wound gape (Video 10.28.2).<sup>95–97</sup>

Postoperative drops consist of discontinuation of all oral or topical glaucoma medications to be added back as needed, a fourth-generation fluoroquinolone four times per day for 1 week, prednisolone acetate 1% four times a day (tapered weekly), and pilocarpine 1% or 2% four times a day for 1 month, then three times per day for 1 month, and reduced to twice per day before being discontinued. The reason for extended pilocarpine use is to flatten the iris and draw the scleral spur posterior to reduce the chance of peripheral anterior synechiae or to break adhesions.<sup>98</sup> Because most flow occurs where the TM was removed,<sup>99</sup> a significant pressure-lowering effect from pilocarpine-mediated tension on the scleral spur and meshwork cannot be expected after trabectome surgery.<sup>100</sup>

## Results

Trabectectomy ab interno with the trabectome has established itself as a safe and effective MIGS procedure for adult and infant glaucomas with over a decade of experience since its invention. To date, more than 50 000 cases have been documented, more than 5000 of which were recorded in detail and followed up long term via a repository that is made available to researchers.

The largest study came from the manufacturer's database with 4659 cases (stand-alone and combined) and detailed a mean IOP decrease of 26% from a baseline of  $23.1 \pm 8$  on 1.5 fewer medications at 75 years.<sup>101</sup> Only 7% of cases required reoperation. IOP less than 21 mm Hg with a 20% decrease occurred in 56% for stand-alone trabectome cases at 75 years and in 85% of combined cases at 5 years. A meta-analysis found that stand-alone trabectome lowered the mean IOP by 10 mm Hg and combined cases by 6 mm Hg, while decreasing the number of medications by one.<sup>102</sup> The only identified risk factors for failure are a lower baseline IOP<sup>103</sup> and younger age.<sup>104</sup> Previous laser trabeculoplasty was shown not to reduce the efficacy of trabectome,<sup>103</sup> and a failed trabectome did not increase the failure rate of a subsequent trabectectomy ab externo.<sup>105</sup> Our experience with 200 consecutive trabectome surgeries for patients who would normally have received a tube or trab (open or closed angle glaucoma, including failed trabectomies and tube shunts), suggest that a final IOP of less than 18 mm Hg can be achieved in 81%, less than 15 mm Hg in 52%, and less than 12 mm Hg in 27%.<sup>163</sup>

## Phaco Combined With Trabectome

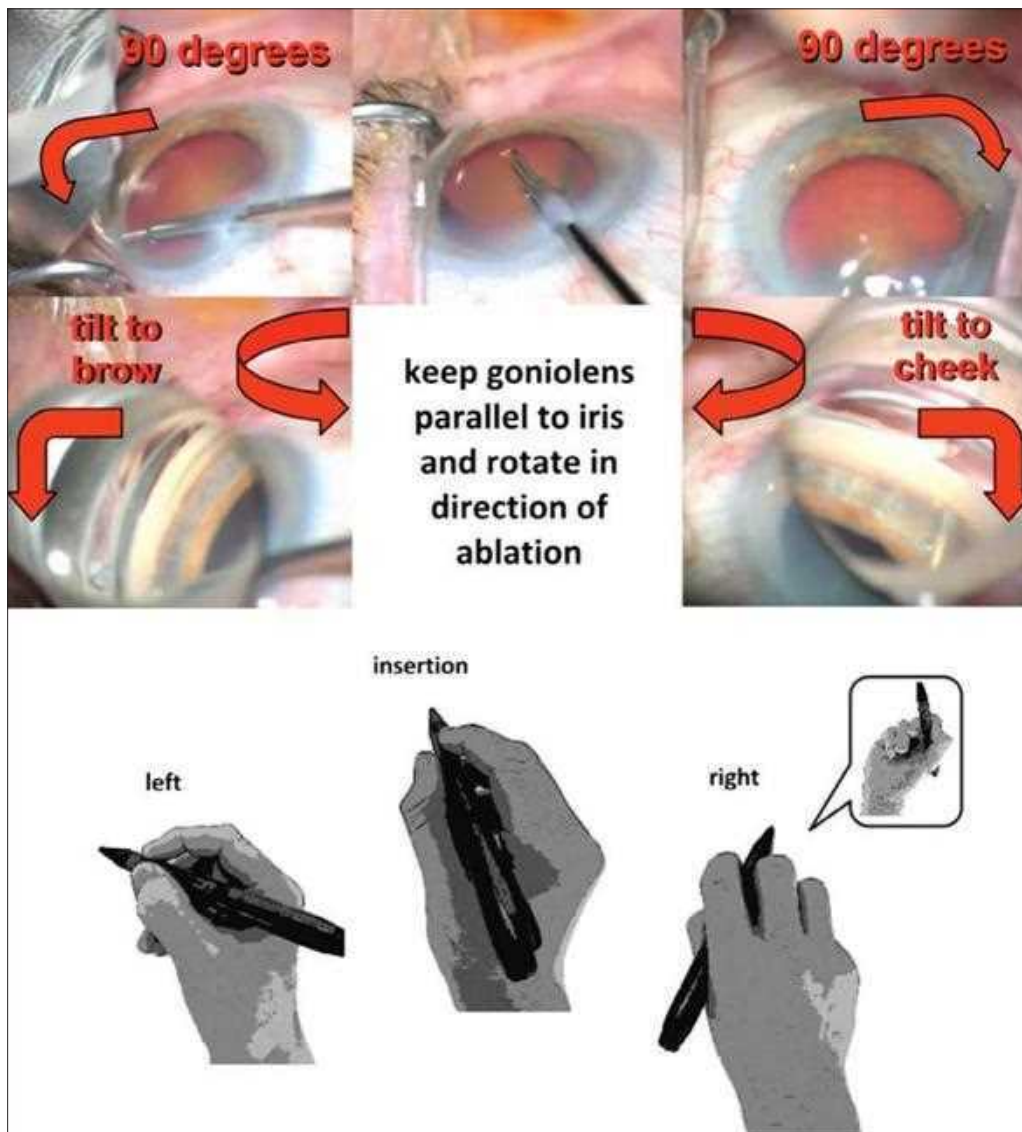

In contrast to trabecular microbypass stents,<sup>5</sup> adding cataract surgery to trabectome surgery does not provide any significant additional IOP reduction.<sup>106,107</sup> As a bypass leaves most of the TM untouched, there may be a trabeculoplasty-like effect from cataract surgery (ultrasound, trabecular meshwork stretch) that occurs to a much smaller degree when up to half of the TM is removed by trabectome surgery.<sup>63,108</sup> A recent review of 498 patients undergoing phaco–trabectome surgery demonstrated a greater reduction in IOP in more severe glaucoma, as well as corticosteroid-induced glaucoma<sup>109,110</sup> and pseudo-exfoliative glaucoma.<sup>111,112</sup> The focus on a percentage reduction is misleading because of the increase of outflow facility that is only limited by posttrabectome outflow resistance. Cases with a high preoperative IOP can be expected to drop close to a similar postoperative IOP of almost 16 mm Hg as cases with a lower preoperative IOP.<sup>109,113</sup>

## Trabectome Alone in Pseudo-Phakic and Phakic Eyes

The lens status seems to have no significant impact on IOP reduction. In a review of 235 patients with pseudo-phakia undergoing trabectome surgery compared with 352 patients undergoing phaco–trabectome, individuals who had undergone phaco–trabectome had only slightly lower IOPs ( $0.73 \pm 0.32$  mm Hg) compared with patients who underwent trabectome alone.<sup>106</sup> In a prospective study of 261 patients undergoing trabectome or phaco–trabectome, there was a trend toward a greater benefit in phaco–trabectome compared with trabectome alone in phakic or pseudo-phakic eyes.<sup>114</sup> However, in a review of 255 patients with phakia undergoing trabectome compared with 498 patients undergoing phaco–trabectome, patients with phakia had a 21% reduction in IOP compared with an 18% reduction in patients undergoing stand-alone phacoemulsification with a statistically similar IOP and medication load, suggesting that phaco itself may not contribute significantly to IOP reduction.<sup>107</sup>

See clip:  
10.28.2

**Fig. 10.28.10** The goniolens should be rotated into the direction of ablation to ablate nearly 180°. Gonioscopic prism power and angle view at the terminal ends is increased by lifting the lens off the cornea to float in the pool of saline. The lower part of the diagram illustrates proper grasp of the instrument as well as increasing pronation during the second half of the ablation.

### Trabectome and Goniosynechialysis in Narrow Angles and Angle Closure

Previously, it was hypothesized that angle-based glaucoma surgery in patients with narrow angles would lead to synechiae and fibrosis, so this has been considered a relative contraindication to trabectome surgery. However, a retrospective review of 671 patients undergoing either trabectome or phaco-trabectome offered evidence that trabectome surgery can be successful even in these patients after 1 year. Patients with a narrow angle (Shaffer grade  $\leq 2$ ) had a 42% IOP reduction after trabectome and a 24% reduction in IOP after phaco-trabectome. Similarly, patients with an open angle (Shaffer grade  $\geq 3$ ) had a 37% reduction in IOP after trabectome and a 25% reduction in IOP after phaco-trabectome. There was no statistically significant difference between the groups in IOP, the number of medications, or success rates, suggesting that trabectome surgery is a viable option for patients with narrow angles.<sup>115</sup>

### Trabectome After Failed Trabeculectomy or Tube Shunt Surgery

Reoperations after failed trabeculectomy or tube shunt are some of the most challenging surgeries for a glaucoma specialist. Trabectome may be a suitable alternative to a revision or repeat filter or shunt. In a retrospective review of 20 patients undergoing trabectome surgery after prior failed tube shunt, there was a statistically significant reduction in IOP from 23.7  $\pm$  6.4 mm Hg to 15.5  $\pm$  3.2 mm Hg at 12 months. The authors report an 84% success rate at 12 months, with only three patients requiring further surgery.<sup>116</sup> In a retrospective review of 73 patients undergoing trabectome surgery after failed trabeculectomy, there was a 28% reduction in IOP following trabectome and a 19% reduction following phaco-trabectome, with a 1-year success rates of 81% and 87%, respectively.<sup>117</sup> Another review of 60 patients undergoing trabectome after failed trabeculectomy demonstrated a 36% reduction in IOP and a 14% decrease in medications, with 25% of patients requiring further surgery in the course of follow-up.<sup>118</sup> Although

these studies were limited by their retrospective nature and the relatively small number of patients included, the results suggested that the distal outflow tract is patent and functioning contradicting the assumption that an unused outflow system atrophies. Presumably, this assumption was the product of a misinterpretation of the high IOP that often follows closure of the drainage cleft of a cyclodialysis, a historical surgery now rarely performed.<sup>119–121</sup>

### Adjuvant Trabectome Surgery at the Time of Tube Shunt Surgery

Finally, with its favorable safety profile, trabectome surgery may be used as an adjuvant during tube implantation. In a matched comparison of 117 patients undergoing Baerveldt tube implantation alone versus 60 patients undergoing Baerveldt combined with trabectome surgery, both groups showed similar IOPs and visual acuities at each postoperative time point.<sup>122</sup> However, the combined group required fewer IOP-lowering drops at each time point. Adjuvant trabectome surgery may improve the quality of life by reducing medication burden. Results from Ahmed tube implantations were similar<sup>123</sup>; trabectome surgery plus two medications reduced the IOP by 12 mm Hg, whereas Ahmed implantation plus four medications lowered IOP by 15 mm Hg.

### Trabectome Surgery in Severe Glaucoma

When trabectome surgery outcomes are stratified by glaucoma severity, patients with more medications, a higher baseline IOP and worse visual field experience a larger IOP reduction than subjects with less aggressive glaucoma.<sup>109,113</sup> A glaucoma index was created that captures the clinical treatment resistance and the risk by combining baseline IOP, the number of medications, and visual field status. The analysis of 843 patients indicated that patients in the most advanced glaucoma group and higher baseline IOP had a threefold larger IOP reduction than the ones in the mild glaucoma group. Individuals with advanced glaucoma had a lower success

rate of 71% compared to ones with mild glaucoma who had a success rate of 90%. Age, pseudo-exfoliation, and corticosteroid-induced glaucoma were found to be significantly associated with a greater IOP reduction, with Hispanic ethnicity and cup-disc ratio showing a weaker association.<sup>109,113</sup> Traditional filtering surgeries remain a good option after failed trabectome surgery,<sup>124</sup> whereas SLT is less successful in this situation.<sup>125</sup>

One of the main benefits of trabectome surgery is the greatly reduced risk of vision-threatening complications typical to traditional glaucoma surgeries while being effective in achieving average pressures of about 16 mm Hg. The most common complication is reflux of blood from the collector channels, which occurs in nearly all cases, indicating a free and unobstructed communication with the drainage system.<sup>104</sup> There are three published cases detailing surgical intervention for hyphema because of an associated IOP spike.<sup>126,127</sup> The vast majority of microhyphemas and layered hyphemas are cleared by 1 week. Spontaneous hyphema has been reported in a small case series up to 31 months after trabectome,<sup>126</sup> but in our experience with over 900 cases, only two patients had symptomatic late-onset hyphema. In one study, the second-most common complication was PAS, which was found, to some degree, in 24% of patients.<sup>128</sup> Transient postoperative IOP spikes of at least 10 mm Hg have been seen in 4%–10%<sup>26,129</sup> of patients consistent with other MIGS procedures. Other complications reported in less than 1% of reported cases include cyclodialysis cleft,<sup>104</sup> transient hypotony, lens injury, aqueous misdirection,<sup>130</sup> and choroidal hemorrhage.<sup>130</sup>

Two studies that did not use matching to balance groups compared the results of two second-generation iStents to trabectome. The first combined all cases with phaco ( $n = 54$ ) and found that from a mean baseline close to 22 mm Hg in both groups, the IOP decreased by 30% after trabectome and by 34% after two iStents with a similar and small ( $<1$ ) medication decrease after 1 year, and the difference between groups was not statistically different.<sup>131</sup> Another retrospective study found that from a similar baseline IOP close to 20 mm Hg, after 12 months the IOP decrease was 27% with phaco combined with two second-generations versus only a 16% decrease with phaco combined with trabectome surgery.<sup>132</sup> The IOP was 18 mm Hg or less off medications in 14% with trabectome versus 39% for stents ( $P = 0.006$ ). Unfortunately, neither of these studies used case matching to account for the number-one risk factor for failure, lower baseline IOP.<sup>50</sup>

## Other Ab Interno Trabeculectomy and Trabeculotomy Techniques

There are several other surgical options that are similar (Fig. 10.28.11). A key feature of the trabectome is a ramping “footplate” that provides the key function of lifting the TM and putting it on a slight stretch, positioning the tissue for maximal discharge effect from above while protecting underlying tissue.<sup>133</sup> It represents the refinement of a mechanical goniectomy instrument.<sup>86</sup> While the plasma created at the tip of the electro-surgical trabectome molecularizes the TM and is the more atraumatic and drag-free TM removal technique, it does require a high-frequency generator that is not necessary with the goniectome<sup>86</sup> or the dual blade introduced a few years later.<sup>134</sup> This device has recently been reintroduced for use in operating rooms where a high-frequency generator is not available<sup>135,136</sup> in the form of the Kahook dual blade and a goniotome with active irrigation and aspiration.<sup>137</sup> Preclinical investigations on ab interno trabeculectomy with the trabectome and a passive dual-blade device demonstrated a similar decrease in IOP in an eye perfusion model.<sup>135</sup> A key differentiator among these instruments, however, is the active irrigation and aspiration system that facilitates visualization,<sup>137</sup> a challenge that is well described in the pediatric goniosurgery literature.<sup>138–140</sup> A comparison in a pig eye model

indicated higher average outflow after the active dual-blade goniectome compared to the Kahook dual blade, but the results were limited by eye number and did not reach statistical significance.<sup>137</sup> Gonioscopy-assisted transluminal trabeculotomy (GATT) requires a gonioscope and a suture or illuminated catheter. A 1–2 mm goniotomy is created to thread either a microcatheter or suture (i.e., 4-0 nylon)<sup>141</sup> for 360° through SC. The suture is then externalized, creating a 360° trabeculotomy. In 41 patients with POAG, the IOP fell by 39% from a baseline 26 mm Hg on one less medication.<sup>142</sup> IOP less than 21 mm Hg with a 20% decrease from baseline was achieved in 70% of cases, whereas 12% of patients required reoperation within 1 year. All complications (i.e., hyphema in 25%) spontaneously resolved by the 3-month visit.

## SUBCONJUNCTIVAL MICROSHUNTS

### Concept

A subconjunctival microshunt can be seen as a consequential improvement on a stent that is meant to make the sclerectomy step in trabeculectomy easier, the Ex-Press (Alcon, Fort Worth, TX) (Fig. 10.28.12). The Ex-Press was found to confer only small advantages in surgery and postoperative management compared with trabeculectomy while introducing new challenges as a result of introducing a foreign body into the eye.<sup>143</sup> Nevertheless, these devices take advantage of the more than half a century of experience with subconjunctival filtration as an alternative to the natural outflow pathway, which includes diffusion through the conjunctiva, diffusion into the venous system of the sclera and conjunctiva, and potential lymphatic pathways.

**Fig. 10.28.11** Active and passive dual-blade goniectomes (DBGs). The active dual-blade goniectome (active DBG, top<sup>86,134</sup>) has two irrigation ports that maintain the chamber (blue arrows). The trabecular meshwork (TM) is put under stretch by an angle-shaped ramp and excised by a left blade and a right blade. The cut trabecular meshwork strip, blood, and debris are aspirated into the tip (red arrow). The passive dual-blade goniectome (passive DBG, bottom<sup>136,137</sup>) requires viscoelastic to maintain the anterior chamber. It also puts the TM under stretch by an angle-shaped ramp and cuts the TM with a left blade and a right blade. The TM strip can be left attached in the eye or amputated and extracted with microforceps.

**Fig. 10.28.12** Subconjunctival microshunt XEN. (A) Size comparison—the XEN shunt is approximately twice as thick as a human hair. (B) Insertion into the subconjunctival space. (C) Anterior-segment optical coherence tomography of a shunt showing subconjunctival insertion. (Courtesy AqueSys, Inc., Irvine, CA.)

There are two subconjunctival microshunts with published results. The XEN (AqueSys, Irvine, CA) consists of a 6-mm long, permanent, hydrophilic porcine gelatin tube that is cross-linked with glutaraldehyde. This material is pliable and considerably smaller than traditional aqueous shunts, which may prevent problems associated with larger drainage devices, most importantly erosion and corneal endothelial damage.<sup>144</sup> Three different versions offer increasing bore size for increased outflow in more advanced cases from the Nano to the Mini to the standard (largest bore). The XEN is inserted gonioscopically, preserving the integrity of the patient's conjunctiva with less inflammation and subsequent fibrosis. The InnFocus microshunt (InnFocus Inc., Miami, FL) shares a similar concept, has a 70-mm diameter, 8.5-mm long lumen made of poly(styrene-bloc k-isobutylene-block-styrene) but is inserted externally.<sup>145</sup>

## Technique

The XEN device is inserted under gonioscopic view in a manner similar to the bypass shunts explained above. The XEN is a 25- or 27-gauge needle and designed to exit into the subconjunctival space approximately 2.5–3.5 mm posterior to the limbus. Future studies may incorporate mitomycin C.<sup>146</sup> The external approach for the microshunt requires a limbal 6–8 mm wide sub-Tenon's dissection, followed by topical mitomycin C on sponges (0.4 mg/mL mitomycin C for 3 minutes).<sup>145</sup> Next, the entry site is chosen 3 mm posterior to the limbus for a 1 × 1 mm partial thickness scleral incision. Either a 25- or 27-gauge needle is used to enter this incision and advanced into the angle. The microshunt is advanced through the needle tract by using forceps until 2–3 mm of the tube is in the anterior chamber. The tubes are not sutured in place. The limbal peritomy is closed with 10-0 nylon sutures.

## Results

The XEN was combined with phaco in 32 patients and showed a mean 29% IOP decrease on three fewer medications from a baseline of 21 mm Hg on three medications after 12 months.<sup>147,148</sup> An IOP 18 mm Hg or greater off medications was achieved in 90% of cases. The only complications reported were bleeding in anterior chamber (87%) or at the scleral incision (90%), and in two cases (6%), the stent could not be inserted.

Another study on the microshunt (n = 23) showed a mean 55% IOP decrease on two fewer medications from a higher baseline of 24 mm Hg on two medications after 36 months.<sup>145</sup> IOP 14 mm Hg or less (on an unspecified number of medications) was achieved in 82% at 3 years. Transient hypotony (13%), shallow anterior chamber (13%), and choroidal detachment (9%) all resolved without intervention. There were two cases (9%) of elevated IOP, one of which was treated by irrigating the tube through the anterior chamber to clear fibrin. More serious complications included one case each of vitreous hemorrhage and bleb leak, with no necessary interventions reported. Reoperation (a second microshunt) was performed in one case, for an encapsulated bleb. Interestingly, 22% of the blebs appeared to be flat yet retained good IOP control without intervention. No patient lost more than one line of vision.

## SUPRACHOROIDAL DRAINAGE DEVICES

### Concept

Aqueous humor is produced by the ciliary body and exits the eye through either the TM or the uveoscleral route. Although traditional glaucoma surgical techniques have targeted the conventional trabecular outflow route, some newly developed ones use space-retaining devices to increase the uveoscleral outflow route.

Because in classic glaucoma surgery aqueous humor is shunted to a pocket covered only by thin conjunctiva and Tenon's capsule, fibrosis and infection remain a lifelong concern.<sup>149</sup> In an attempt to avoid these problems, suprachoroidal devices have been developed to drain aqueous humor into a potential space—the suprachoroidal space. This approach takes advantage of the hydrostatic pressure gradient between the anterior chamber and the suprachoroidal space.<sup>150</sup> Once the aqueous reaches the suprachoroidal space, the fluid is thought to leave mainly through one of three routes: (1) Hypoechoic pockets<sup>7</sup> at the tail end of shunts may represent fluid leaving through the choroidal vasculature.<sup>151</sup> (2) Successful shunts may have larger and denser conjunctival microscopic tracks within a spongy sclera that could be the result of a spongy sclera from surgical manipulation,<sup>152</sup> suggesting that intrascleral egress routes lead to subconjunctival drainage. (3) Finally, vasculature sharing features with lymphatic

vessels have been seen on histology within and around suprachoroidal shunts.<sup>151</sup>

The idea of reducing IOP by diverting fluid into the suprachoroidal space was first realized at the beginning of the twentieth century when Ernst Fuchs identified the cyclodialysis cleft.<sup>153</sup> This approach was complicated by an unpredictable closure of the cleft responsible for aqueous humor drainage, resulting in drastic and painful pressure spikes. Extended function seemed possible with a cleft maintainer. However, the materials and size were not tolerated well enough and led to poor long-term outcomes.<sup>154</sup> Advances in engineering and material science have now allowed for the reduction of bioreactivity and drainage device size. These devices can be implanted via the ab externo or ab interno approach and preserve the TM and can spare the conjunctiva.

## Ab Externo Suprachoroidal Shunts

### SOLX Gold Micro-Shunt

The current generation SOLX Gold Micro-Shunt (GMS Plus; SOLX Ltd., Waltham, MA) is a nonvalved, 24-karat gold implant, which weighs 9.2 mg and is 0.06 mm thick, 5.5 mm long, and 3.2 mm wide posteriorly with interior channels (Fig. 10.28.13).

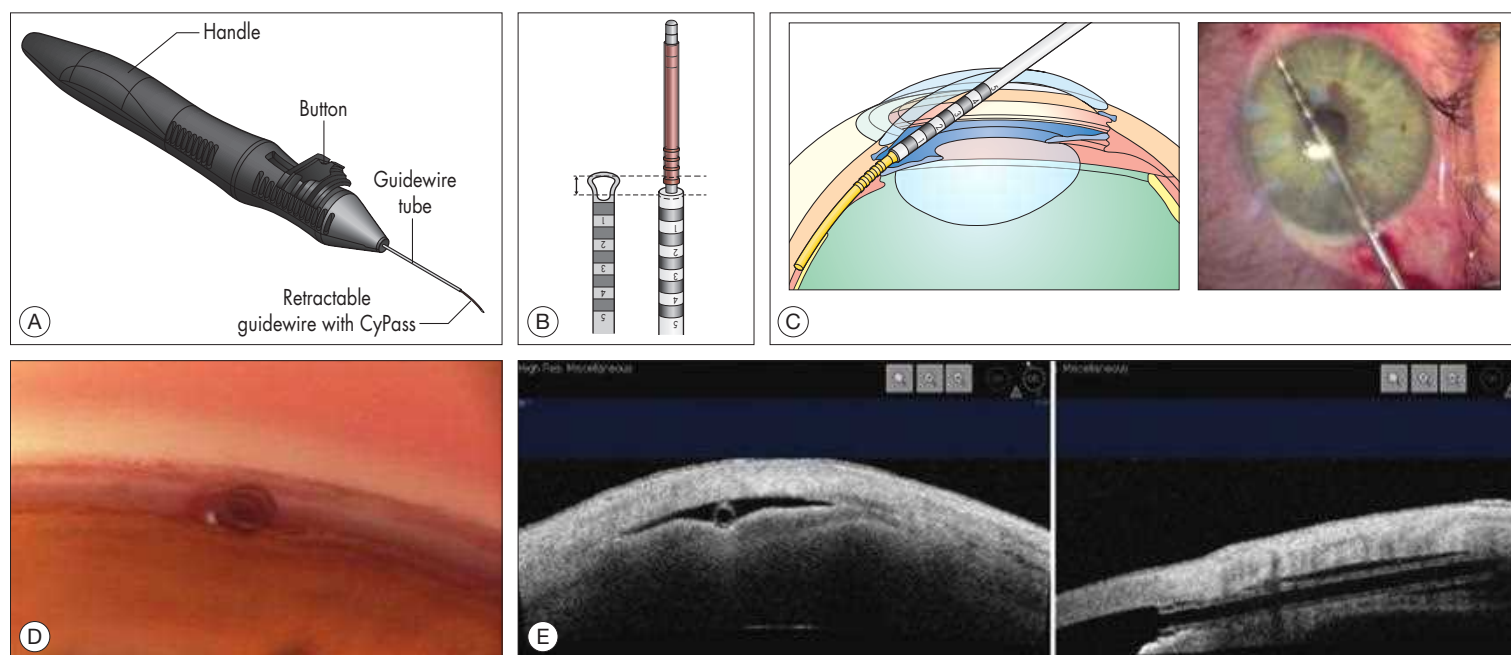

### Technique

GMS implantation surgery is performed under cover of local anesthesia with the use of sub-Tenon's or peribulbar injections. The GMS can be implanted in any quadrant as long as the scleral tissue in the area of surgery is healthy. After a 4-mm fornix-based conjunctival peritomy, a scleral incision of about 3.5 mm is created 2 mm posterior from the limbus. A 95% thickness scleral pocket is then created posterior and anterior to the incision to accommodate the GMS without entering the anterior chamber. The remaining thin layer of sclera overlying the choroid at

**Fig. 10.28.13** SOLX GMS suprachoroidal gold shunt that is implanted via an ab externo approach. (A) The head and shoulder have flow channels that open toward the anterior chamber, whereas aqueous egresses posteriorly. (B) The shunt in its final position in the chamber angle. (C) Implantation is possible at any clock hour as in this patient who had previous surgery superiorly (note previous superior iridectomy). (Courtesy Solx Inc.)

**Fig. 10.28.14** Suprachoroidal shunt CyPass. (A) CyPass preloaded in an injector. (B) Goniometer for implantation without goniolens. (C) Demonstration of implantation without goniolens. (D) CyPass in the chamber angle after implantation and (E) surrounded by aqueous humor in the suprachoroidal space as visualized by high-resolution ultrasound biomicroscopy. (Courtesy Transcend Medical, Inc.)

the base of the initial incision is cut to expose the choroid. The GMS is inserted through the scleral tunnel into the anterior chamber. The anterior drainage openings should be visible and clear of angle structures and the incisions are closed in a watertight fashion.

### Results

The first report was a prospective 12-month study of 38 patients who had glaucoma as well as uncontrolled IOP (half had already failed previous incisional surgery).<sup>7</sup> The study demonstrated a 33% decrease in mean IOP from a baseline of 28 mm Hg on 0.5 fewer medications. Complications included shunt exposure, synechiae, or exudative retinal detachment in three patients. Hyphema occurred in 21% and resolved spontaneously within 2 days in all cases. Choroidal detachment occurred in 11%, and all resolved spontaneously; corneal edema occurred in 4%.<sup>155</sup> There have been two cases of serous retinal detachments that lead to device explantation.<sup>7,155</sup>

## Ab Interno Suprachoroidal Shunts

### CyPass Micro-Stent

The CyPass Micro-Stent (CMS; Transcend Medical, Menlo Park, CA) is a polyamide fenestrated microstent that is implanted under gonioscopic view just posterior to the scleral spur to directly connect the anterior chamber to the suprachoroidal space to increase uveoscleral outflow (Fig. 10.28.14).<sup>156</sup>

### Technique

CMS implantation is done via an ab interno approach through a clear corneal incision. Initially, the anterior chamber is filled with viscoelastic to maintain the chamber and expand the angle. The CMS device is loaded onto a retractable, curved guide wire. This device can be inserted by using a goniometer (markings are on the inserter) to estimate insertion position and depth under gonioscopic view. After fashioning a clear corneal incision, the guide wire is designed to bluntly dissect the ciliary body from the sclera and to create a micro-cyclodialysis cleft which will serve as a passage into the supraciliary space. Once the stent is correctly positioned, the guide wire is retracted and withdrawn from the eye. Upon retraction of the guide wire from the implant, the implant re-forms to its original, straighter configuration. Correct placement can be evaluated by using UBM or anterior-segment optical coherence tomography.

### Results

Two large studies on the CMS have been performed. One only provided washed-out IOP values ( $n = 374$ ) and compared phaco to combined phaco-CMS. The combined group had a 30% IOP decrease on one less medication from a baseline of 24 mm Hg on 1.4 medications.<sup>157</sup> After 24 months, an IOP 18 mm Hg or less off medications was achieved in 67%

of combined cases versus 41% of phaco cases. There were no statistically significant differences in complications between the two groups. There was transient hypotony in 3% of combined cases, obstruction in 2%, and device migration in 0.5%. Another study ( $n = 167$ ) divided results based on whether baseline IOP was less than 21 mm Hg.<sup>158</sup> Cases with baseline IOP 21 mm Hg or greater (mean 26 mm Hg) had a 37% IOP decrease on an average of one less medication, whereas the other group (mean IOP 17 mm Hg) had a 5% decrease on 1.5 fewer medications. This suggests that as with other MIGS, cases with higher baseline IOP have better results when measured by IOP and medication reduction.<sup>50</sup> Possible reasons for this are differing surgical indications (i.e., the surgeon and the patient may consider stopping a medication with no change in IOP as a success) leading to different patient populations. Another possibility (that may, in the future, be proven with aqueous angiography) comes from theoretical modeling suggesting that at higher baseline IOPs, a greater proportion of aqueous outflow will exit through a TM bypass.<sup>159</sup>

### iStent G3 Supra

The iStent G3 Supra (Glaukos, Laguna Hills, CA) is the latest third-generation iStent device and is very similar in design to the CMS (Fig. 10.28.15). The device is 4 mm long and is made of heparin-coated polyethersulfone and a medical-grade titanium sleeve.<sup>156</sup> It is designed to be implanted via an ab interno approach into the suprachoroidal space. Clinical studies have not yet been reported.

## CONCLUSIONS

Trabeculectomy has been the gold standard in the first-line surgical management of glaucoma for the last 30 years, and more recently, glaucoma drainage devices have gained popularity partly because of a decreased need for postoperative management and greater predictability.<sup>160</sup> Despite refinements in technique and the introduction of adjunctive measures, the complication rates remain relatively high and long-term success moderate. Because MIGS provides safer surgical profiles, it offers the ability to intervene earlier, mitigating the perennial issue of noncompliance and associated costs. MIGS is highly standardized and considerably faster compared with standard incisional surgery and can be easily combined with cataract surgery, with or without toric lens implantation to correct astigmatism. The incision used is often the same as that used for cataract surgery and allows for accurate calculations of surgically induced astigmatism.

The decrease in risks, including that of hypotony and related complications (e.g., suprachoroidal hemorrhages or effusions), is one of the main benefits of these newer glaucoma procedures, but it comes at the cost of a reduced ability to reliably achieve IOPs below 15 mm Hg without additional medications. However, it is notoriously difficult to achieve very low

**Fig. 10.28.15** iStent G3 Supra. (A) Size comparison on the fingertip. (B) High-power view. The device has an intake composed of a different material and a tail with retention rings. (Courtesy Glaukos Corp.)

**Fig. 10.28.16** Cross-section showing iStent in Schlemm's canal and Hydrus implant. (A) iStent in Schlemm's canal (white arrow) and Hydrus implant on the right (B). In (B), note that because of septations in the canal, the Hydrus is stenting open a portion while compressing another portion inferior to it (white arrow). C, cornea; CC, collector channel; SC, Schlemm's canal; TM, trabecular meshwork (Courtesy Glaukos Corp.)

target pressures even with classic glaucoma surgical procedures. Even if the probability of achieving an IOP of 12 mm Hg or less after MIGS is only 37% (or 50% for pseudo-exfoliative glaucoma), it may still benefit the patient to first try MIGS combined with phaco and then proceed to more risky trabeculectomy or aqueous shunt surgery if target pressures cannot be achieved even with eyedrops. As internal MIGS does not violate the conjunctiva, the success rate of subsequent trabeculectomy likely remains unchanged.<sup>105</sup>

The advantages of MIGS are compelling, but to date, no randomized controlled trials have compared them with classic procedures. This observation is similar to the more technology-dependent phaco, which revolutionized cataract surgery and drastically reduced the number of extracapsular cataract extractions performed.

The IOP differences between the different MIGS modalities may be directly related to how many individual collector outflow segments are accessed. For instance, iStent G2 is a space maintainer for a pointed trabeculotomy, whereas iStent G1 is a longer device, which is followed by the 8-mm Hydrus (spanning 45°), the 15-mm Hydrus (150°), the trabectome (120–180°), and GATT (360°). Increasing efficacy with increasing segment access may be reflected in the growing likelihood of postoperative hyphema, which indicates a flow reversal in the collector channels as a result of an inverted pressure gradient (lower in the anterior chamber than in the episcleral venous system).

There are distinct disadvantages to drainage devices and stents in the eye, whether they are placed subconjunctivally (tube shunts) or into SC (MIGS stents discussed in this chapter). As well known from interventional radiology, stenting devices can block the branching vessels, compress the adjacent lumina, and obstruct the lumen they are intended to maintain (Fig. 10.28.16). Hardware may also serve as a nidus for infection.

Over time, even precious metals or other inert materials, such as silicone, can stimulate a foreign body reaction and fibrosis. The TM does have the ability to present antigens but has been invoked in induced tolerance (anterior chamber-associated immune deviation).<sup>161</sup>

Similar to larger vessels treated in interventional radiology and cardiology, outflow tract anatomy can vary widely, and it will likely become standard to image each patient's specific outflow tract before stent or scaffold implantation, as can be done with readily available spectral-domain optical coherence tomography.<sup>1,28,92,162</sup> Advances in microengineering and imaging

technology and a better understanding of glaucoma pathogenesis have enabled the use of new surgical modalities that allow for tapping into the natural drainage system directly.

# Trabeculectomy

Cynthia Mattox

# 10.29

**Definition:** A surgical procedure featuring a partial-thickness scleral flap that creates a fistula between the anterior chamber and the subconjunctival space for filtration of aqueous fluid and the creation of a conjunctival bleb in an effort to lower intraocular pressure.

## Key Features

- Bleb formation.
- When successful, lowers intraocular pressure significantly from preoperative levels.
- Wound healing influences success.
- Meticulous intraoperative technique is required.
- Intense postoperative observation and management is necessary.

## Associated Features

- Antimetabolites (mitomycin C or 5-fluorouracil).
- Hypotony.
- Choroidal detachment.
- Bleb leak.
- Bleb-associated endophthalmitis.

## INTRODUCTION

Trabeculectomy is the most common form of modern filtration surgery used to lower intraocular pressure (IOP) in a patient with glaucoma. In trabeculectomy, a fistula for aqueous fluid is created between the anterior chamber and the subconjunctival space, beneath a partial-thickness scleral flap, to create an area of “filtration” called the *bleb*. Trabeculectomy techniques have evolved from full-thickness sclerectomy forms of filtration surgery to minimize postoperative complications while achieving the goal of successful lowering of IOP. With all forms of filtration surgery, the most sight-threatening complications, such as suprachoroidal hemorrhage, occur in the setting of hypotony. Surgeons embraced trabeculectomy as a way to avoid hypotony, yet historically, the move to trabeculectomy from full-thickness filtration surgery was gradual, as techniques were developed to achieve ultimate success and adequate IOP lowering for the long term.

Trabeculectomy was originally described by Cairns<sup>1</sup> in 1968 and has continued to be modified as surgical instrumentation and suture have improved in recent decades. Modalities to alter wound-healing fibrosis in the subconjunctival space, such as use of antimetabolites (5-fluorouracil and mitomycin C)<sup>2-8</sup> and laser suture lysis,<sup>9</sup> have continued to offer improvements in postoperative success. Trabeculectomy is still considered the “gold standard” surgery for primary glaucoma filtration because it is effective, relatively low risk, and technically within the skills of the well-trained ophthalmic surgeon. Variations of technique among surgeons and variability in wound-healing among patients are the norm, and it is said that astute and careful postoperative management by the surgeon is key to the successful outcome of trabeculectomy for a patient.

It is helpful to understand the anatomy of a trabeculectomy to recognize the optimal conditions for successful surgery. In many ways, the trabeculectomy is a complicated series of “incisions,” most of which must remain free from healing or scarring to establish a functional filtration

**Fig. 10.29.1** Fornix-based trabeculectomy.

bleb.<sup>10</sup> In fact, the only incision that requires complete healing is the conjunctival incision, either at the limbus in a fornix-based flap or at the fornix in a limbal-based flap. Otherwise, the iridectomy, sclerectomy, underside of the partial-thickness scleral flap, the sides of the scleral flap, and the extremely important surface area between the episclera and conjunctiva must remain free of obstruction to allow aqueous fluid to migrate through the fistula (Fig. 10.29.1).

Although the goal in trabeculectomy is to establish a subconjunctival filtration bleb that lowers the IOP sufficiently, the bleb itself is the cause of many of the late-onset complications that may occur. Blebs can leak, become infected and induce endophthalmitis, or cause chronic discomfort (Fig. 10.29.2). Antimetabolite use increases the risk of leaking and infection because of the permanent changes in the conjunctiva that promote a thin-walled bleb<sup>11,12</sup> (Fig. 10.29.3). Yet antimetabolites offer a more successful long-term lowering of IOP in patients who are at high risk for filtration failure and in primary trabeculectomies.<sup>7,8</sup> It is the risks of the established bleb that have led to the development of non-bleb-forming filtration surgeries. The main disadvantage of non-bleb-forming procedures, where aqueous is shunted to alternative outflow pathways, such as the episcleral venous system or suprachoroidal space, is lowering of IOP<sup>13,14</sup> to a less significant level that may not be adequate in some patients and may still allow glaucoma progression to occur (Table 10.29.1). Newer devices that allow access to the subconjunctival space with minimal or no (via ab interno insertion through the angle) incisions in the conjunctiva have also been instituted in an attempt to improve the morphology of the bleb and minimize complications. In recent years, after publication of the findings of the randomized Tube Versus Trabeculectomy Study for eyes with previous surgery, as well as the ongoing Primary Tube Versus Trabeculectomy Study, surgeons are recognizing that glaucoma drainage implant surgery may rival or improve on the long-term results of trabeculectomy, although controversy remains about the complication profile for each procedure, and the ideal surgical procedure for advanced glaucoma.<sup>15</sup>

**Fig. 10.29.2** Leaking Bleb With Positive Seidel Sign After Fluorescein Dye Is Applied. See Video 10.29.1.

**Fig. 10.29.3** Example of localized, cystic, thin-walled bleb.

## INDICATIONS

The goal of glaucoma management is to preserve visual function while maintaining or improving the patient's quality of life. When surgery is necessary, trabeculectomy is the procedure of choice for most cases of severe primary glaucomas. Success in glaucoma surgical studies is usually reported as a final IOP <21 mm Hg and/or 30% decrease in IOP, with or without additional medications, even though for many eyes that undergo trabeculectomy the goal is for postoperative IOP control in the low teens. Success with the typical definition in forms of open-angle glaucoma and primary angle-closure glaucomas has been reported in approximately 80% of eyes over 1–2 years, with lower IOP achieved with antimetabolite use.<sup>8,12,16–26</sup> Relatively few studies have evaluated the long-term preservation of visual field and optic nerve function as an outcome measure, yet it seems that glaucoma surgery is successful in this regard for the majority of eyes that have resulted in successful control of IOP.<sup>27</sup>

The decision to offer trabeculectomy is based on the patient's current stage of their glaucoma and the risks for ongoing progression of the disease without further intervention. The rate of progression differs among patients as does the goal for IOP control. Each individual must be carefully evaluated as to the best treatment modality. There are some patients who are likely to need trabeculectomy soon after diagnosis of their glaucoma, yet there are many patients who will never need trabeculectomy even after many years of the disease (Box 10.29.1).

## SURGICAL PLANNING

Surgical planning begins in the office with a careful history, ocular examination, and review of the patient's risk factors for failure (Table 10.29.2).

**TABLE 10.29.1** Trabeculectomy Versus Non-Bleb Filtration Surgery

Advantages	Disadvantages
<b>Trabeculectomy</b>	
Proven long-term success	Wound healing reaction important
Technical skills moderate	Creates a bleb—risk for infection
Gold standard	Creates a bleb—risk for discomfort
Relatively low risk of hypotony	Duration of effect—limited
Instrumentation readily available	More postoperative interventions: laser suturelysis, 5-fluorouracil injections
<b>Non-Bleb Filtration Surgery</b>	
Low risk of hypotony	Less intraocular pressure lowering long term Fewer published reports on long-term success
No bleb or bleb complications	Some techniques more technically difficult, time-consuming in operating room
	Need postoperative interventions: iridotomy, Descemet's puncture
	Additional instrumentation and/or devices

**TABLE 10.29.2** Risk for Failure

Average Risk	Moderate Risk	High Risk
POAG	JOAG	Childhood onset
Pseudo-exfoliation glaucoma	Pigmentary glaucoma, mainly due to younger age of patient	Neovascular glaucoma— inflamed eye
Mixed mechanism	Blunt trauma, angle recession	Uveitis, inflammatory
Prior clear cornea phacoemulsification	Conjunctival scarring after phacoemulsification	Conjunctival scarring after ECCE, ICCE
	Neovascular glaucoma— quiet eye	Conjunctival scarring after vitrectomy
	Fellow eye with encapsulated bleb	Fellow eye failed filter
	Combined with phacoemulsification	Prior filter failed
	After acute angle closure	Perforating/penetrating traumas
	Corticosteroid-induced glaucoma	ICE syndrome
	Chronic angle-closure glaucoma	Epithelial downgrowth
Elderly	Middle age	Youth
White, Asian		Hispanic, African descent

ECCE, Extracapsular cataract extraction; ICE, iridocorneal endothelial syndrome; ICCE, intracapsular cataract extraction; JOAG, juvenile-onset open-angle glaucoma; POAG, primary open-angle glaucoma.  
(Sources: Skuta et al.<sup>7</sup>; Mietz et al.<sup>28</sup>; AGIS Investigators<sup>29</sup>)

### BOX 10.29.1 Indications for Trabeculectomy

- Intraocular pressure (IOP) too high to prevent future glaucoma damage and functional visual loss
- Documented progression of glaucoma damage at current level of IOP with treatment
- Presumed rapid rate of progression of glaucoma damage without intervention
- Poor compliance with medical therapy: cost, inconvenience, understanding of disease, refusal
- Intolerance to medical therapy because of side effects

On the basis of this assessment, the surgeon will plan the approach to surgery, including fornix-based or limbal-based conjunctival flap dissection, placement of the scleral flap and sclerostomy, need for and type of antimetabolite, tightness of the scleral flap sutures to titrate the amount of aqueous fluid egress in the early postoperative period, need for releasable scleral flap sutures, and any preoperative treatments.

## PREOPERATIVE FACTORS TO CONSIDER

Preoperative factors that need to be considered are given in Table 10.29.3.

TABLE 10.29.3 Preoperative Factors

Location	Finding	Considerations
External/adnexa	Abnormal lid position or lagophthalmos	Increases risk for exposure, thinning, discomfort, and infection of bleb If prior blepharoplasty/ptosis repair, conjunctival fornix may be under tension
	Blepharitis	Increases risk for infection in the early and late postoperative periods
Conjunctiva	Allergy, toxicity	Discontinue any drops causing topical toxicity for several weeks prior to surgery. Consider preoperative topical corticosteroids to quiet eye
	Dry eye, keratoconjunctivitis sicca	Should be treated. Punctual plugs, omega-3s, and cyclosporin are considered. May be more at risk of infection in the early or late postoperative period
Conjunctival scarring <sup>a</sup>	Prior pterygium or tumor removal	Less mobile conjunctiva overall, and scarring nasally
	Prior ECCE surgery	Entire limbal area, conjunctiva and sclera, may be scarred
	Prior scleral tunnel phacoemulsification	Localized area of limbal scarring, may be able to position trabeculectomy flap to one side of tunnel
	Prior pars plana vitrectomy	Localized areas of conjunctiva scarring posterior to limbus, and/or entire limbal area may be scarred
	Prior scleral buckle	Entire limbal and posterior conjunctiva is scarred
	Trauma	Careful inspection for wound, scarring
Cornea	History of herpes simplex virus infection	Consider antiviral coverage during the postoperative period
	Prior penetrating or endothelial keratoplasty	Position trabeculectomy to avoid encountering host-graft interface or peripheral anterior synechiae
Anterior chamber	Uveitis	Treat aggressively prior to and after surgery. Eye often at risk for hypotony because of low aqueous production
Iris, angle	Peripheral anterior synechiae	Gonioscopy to locate and avoid
	Trauma	Avoid sclerostomy near iris dehiscence—may encounter vitreous if zonules absent. Vitrectomy should be considered, if necessary
	Neovascularization	Aggressive treatment before surgery with panretinal photocoagulation, anti-VEGF agents, topical corticosteroids and atropine preoperatively, waiting several weeks for trabeculectomy, if possible. Early hypotony should be avoided to minimize hyphema and fibrin postoperatively
Lens	Aphakic	Vitrectomy should be planned; hypotony should be avoided. There is increased risk of suprachoroidal hemorrhage. Sclera is thin, and conjunctival scarring may occur at the limbus
	Pseudophakic	Sclera is thin at the superior cataract surgery incision Usually less likely to develop postoperative anterior chamber shallowing
	Phakic	Slightly more likely to develop shallow anterior chamber postoperatively Cataract may develop or progress postoperatively
Refractive errors	Myopia	Sclera may be thin. Patients with moderate to high myopia are at risk for hypotony maculopathy when antimetabolites used
	Hyperopia	More likely to develop shallow anterior chamber postoperatively More likely to develop “aqueous misdirection syndrome”
	Prior refractive surgery	Patient may have been had high myopia (see above)
Retina	Comorbid disease	May affect long-term vision; unrelated to glaucoma
Patient issues	Uncooperative, poor understanding of directions	Type of anesthesia, block versus general, should be determined Determination of laser suture lysis or releasable sutures <sup>30</sup> Family, friends, and caregivers enlisted to help with postoperative regimen and follow-up
	Noncompliant	Noncompliance may extend to the postoperative follow-up and medication regimens
	Unrealistic expectations	Extensive counseling preoperatively and postoperatively

ECCE, Extracapsular cataract extraction.

<sup>a</sup>Almost all patients who have conjunctival scarring near the limbus should undergo a fornix-based trabeculectomy. Patients with extensive scarring, neovascular glaucoma, or iridocorneal endothelial syndrome may have better success with glaucoma drainage implantation.

## PATIENT COUNSELING

Long before surgery becomes necessary, it is hoped that the surgeon and the patient have begun a dialogue about the goals for glaucoma treatment. Because glaucoma is usually asymptomatic until far advanced, patients deserve a detailed explanation of the disease in general and the findings in their case in particular. It is likely that the patient realizes that glaucoma is progressing or is at risk for progression, as there has often been an escalation of medical therapy or possibly laser treatment prior to the proposal that trabeculectomy is the next step. At that point, it is appropriate to thoroughly review and discuss the patient's past course and interventions, and the surgeon's rationale for recommending a trabeculectomy. Once the surgical plan is formed, the surgeon and patient should have a thorough discussion about the goals of surgery, the risks, and the usual course of the surgical and postoperative experience. Any individual characteristics of the patient's ocular condition that may influence the surgical outcome should be explained, and the patient should feel well informed and comfortable with the decision to proceed with surgery (Box 10.29.2).

## SURGICAL TECHNIQUES

Perioperative preparation of the patient includes the following:

- Intravenous sedation.
- Adequate anesthesia—topical and subconjunctival, posterior Tenon's, peribulbar, or retrobulbar.<sup>31</sup>
- Positioning to maximize exposure of superior globe.

### BOX 10.29.2 Preoperative Counseling and Informed Consent

- Goals for surgery
  - Expectations for intraocular pressure control
  - Expectations for maintaining, not improving, vision
- Description of surgery
- Experience of surgery
  - Operative—type of anesthesia, expectations for pain, intravenous access, recovery
  - Requirements in postoperative period for drops, activity restrictions, frequent visits
  - Visual difficulties, visual fluctuations during postoperative period
  - Intraocular pressure fluctuations in the early postoperative period
  - Need for postoperative interventions, laser suture lysis, 5-fluorouracil, cycloplegics
  - Duration of postoperative period
- Risks
  - Intraoperative and early postoperative—suprachoroidal hemorrhage, infection, hypotony, shallow chamber, choroidal effusions, bleb leaks, aqueous misdirection, discomfort, cystoid macular edema, astigmatism, hypotony maculopathy, vision loss, failure, need for additional surgery
  - Late postoperative—discomfort, leaks, infection, failure, cataract development or progression, ptosis, permanent vision decrease or loss, need for additional surgery

## Intraoperative Technique: Limbal-Based Conjunctival Flap

The limbal-based conjunctival flap technique is shown in [Fig. 10.29.4](#). The scleral flap has been reapproximated with 2–4 interrupted 10-0 nylon sutures and tightness has been adjusted to allow for a small amount of aqueous oozing at the edges of the scleral flap. Limbal-based conjunctival flap technique, with the conjunctival incision being placed far posteriorly in the fornix, usually 9–10 mm from the limbus, and completed with a running conjunctival suture closure, is less commonly used now due to concerns that this technique creates more restricted blebs prone to late leaks.

**Fig. 10.29.4** Appearance of the Scleral Flap and Conjunctival Dissection Prior to Conjunctival Closure in a Limbal-Based Conjunctival Flap Trabeculectomy. Note the corneal traction suture.

## Surgical Technique: Fornix-Based Conjunctival Flap

See clip:  
10.29.2

The fornix-based conjunctival flap technique is given in [Table 10.29.4](#).

### Avoiding Intraoperative Complications

Careful surgical technique is required to avoid buttonholes of the conjunctiva and to allow minimal manipulations of the conjunctival flap edge. Excessive bleeding into Tenon's capsule is to be avoided because it can absorb blood like a sponge. However, excessive cautery is likely to promote fibrosis and/or scleral thinning. The scleral flap needs to be of sufficient thickness to allow for suture placement without cheesewiring of the suture. Despite its name, trabeculectomy is no longer performed as an excision of the trabecular meshwork. The fistula is less prone to obstruction if the

**TABLE 10.29.4** Surgical Technique: Fornix-Based Conjunctival Flap

Procedure	Instruments
1. Partial-thickness corneal traction suture 7-0 silk <sup>a</sup>	Needle holder, cotton swab for counter traction near limbus
2. Rotate globe inferiorly to maximize superior conjunctival exposure, attach to drape	Hemostat
3. If using injected antimetabolite: Inject desired volume and concentration of mitomycin C (MMC) far superiorly and massage toward limbus, wait minimum of 2 minutes before opening conjunctiva	Syringe with 30-gauge needle and prepared MMC
4. Incise conjunctiva and Tenon's capsule at the limbus, approximately 4–6 mm length. If using modified-Wise conjunctival closure, incision is placed 1 mm posterior to limbus to allow for small “bolster” of conjunctiva at the limbus	Sharp-tip Westcott scissors, toothed forceps Colibri type, nontoothed Max Fine forceps
5. Perform subconjunctival dissection spreading tangentially and radially away from limbus, as broad an area as possible, lifting edge of conjunctiva and dissecting alongside the superior rectus	Rounded Westcott scissors, nontoothed Max Fine forceps holding broad area of conjunctival edge
6. Perform wet field cautery to area of episclera in preparation for creating scleral flap	23-gauge Mentor rounded tip
7. Outline desired width of scleral flap with half-thickness depth	Diamond blade or crescent blade, Colibri
8. Use crescent blade to create a scleral tunnel of the desired width and half thickness, extending into clear cornea, just past end of limbal vessels <sup>b</sup>	Crescent blade, Colibri
9. If using sponge applied antimetabolites: Apply MMC or 5-fluorouracil (5-FU) on 2–6 pieces of sponge, covering a broad area of superior episclera, drape conjunctival flap back toward the incision and hold the edges away from contacting the sponges. Apply MMC for 1–3 minutes based on risk factors and conjunctival condition. Alternatively, apply 5-FU for 5 minutes. Remove sponges, flush with 20–30 mL of balanced salt solution (BSS), dry	
10. If not already released, release corneal traction suture. Perform paracentesis through temporal clear cornea aiming toward 6 o'clock angle <sup>c</sup>	15° super-sharp blade or diamond knife
11. Convert scleral tunnel to a scleral flap by placing two radial incisions, not extending all the way to the limbus	Vannas scissors
12. Lift scleral flap and insert super-sharp blade at farthest anterior part of the tunnel into anterior chamber, angling more vertically than horizontally, move blade steadily across the extent of the base of the bed, taking care not to retract the blade when aqueous gushes forward	Colibri holding scleral flap, super-sharp blade
13. Use Kelly scleral punch to fashion a small central sclerectomy <sup>d</sup>	Kelly punch, Colibri to hold scleral flap
14. Create peripheral iridectomy using jeweler's forceps inserted radially into sclerostomy to grasp iris, and cutting with angled Vannas scissors held circumferentially <sup>e</sup>	
15. Reapproximate the scleral flap with 2–4 interrupted 10-0 nylon sutures. Consider tying first 1–2 sutures temporarily, reinflating anterior chamber with BSS, and adjusting tightness to allow for a small amount of aqueous oozing at edges of scleral flap	Needleholder, Colibri, BSS on 27-gauge cannula and 3-mL syringe
16. Attach corneal traction suture to drape for exposure, if needed	Hemostat
17. Close conjunctival-Tenon's flap at the limbus with any variety of closures, such as a modified-Wise Condon running mattress suture, <sup>f</sup> purse-string wing sutures, and/or interrupted mattress sutures, ensuring watertightness ( <a href="#">Fig. 10.29.5</a> )	Needleholder, curved tying forceps, 10-0 nylon or 9-0 Vicryl
18. Reinflate anterior chamber with BSS and elevate bleb. Check for leaks with 2% fluorescein solution over entire bleb surface	

Two-site combined phacoemulsification and trabeculectomy usually begins with a temporal clear cornea approach to the phacoemulsification (phaco). After the cataract surgery is completed and the corneal incision secured with a 10-0 nylon suture, the surgeon repositions to perform a fornix-based (easier, less time-consuming) or limbal-based conjunctival flap trabeculectomy superiorly.

<sup>a</sup>Most surgeons use this to avoid bleeding from the blind pass of a bridle suture under the superior rectus.

<sup>b</sup>Most surgeons take advantage of the improved exposure of the fornix-based flap to use a familiar technique used with scleral tunnel phaco. Creating a scleral tunnel is also useful in the setting of limbal thinning from a previous ECCE incision, to avoid transecting the scleral flap at the juncture of the previous incision that can occur with traditional dissection.

<sup>c</sup>If performing a combined phaco and trabeculectomy with a single site incision, begin phaco procedure here. Leave viscoelastic in the eye until sclerectomy is performed. Then aspirate viscoelastic, instill intracameral acetylcholine or carbachol, then perform iridectomy and proceed with trabeculectomy closure.

<sup>d</sup>A peripheral iridectomy may not be necessary in pseudo-phakic eyes or when combining trabeculectomy with phaco.

<sup>e</sup>Most surgeons use a punch, whereas others excise a block of tissue. The larger the sclerostomy, the greater is the likelihood of inducing irregular astigmatism. Usually, a 1–2-mm opening suffices.

<sup>f</sup>Again, variation in techniques is common.<sup>32–34</sup> The goal is to achieve watertight closure that will resist deformation of the cornea and a pressure-head of aqueous in the postoperative period. For modified Wise conjunctival closure, see Video 10.29.2 and reference 34.

entry into the anterior chamber occurs well into the peripheral cornea. Meticulous conjunctival closure to avoid wound leaks is imperative.

POSTOPERATIVE CARE

Surgical technique, although extremely important, is just the prelude to the subsequent management that is necessary to achieve a long-term successful filtration surgery (Table 10.29.5). The most critical factor for success is to establish an elevated bleb within the first few days after surgery. Creating a physical separation with aqueous between the conjunctiva and episclera prevents subsequent fibrosis that will limit the surface area available for filtration and ultimately result in inadequate IOP lowering. In fact, in the early postoperative period, the appearance of a bleb is a more important factor to consider than the IOP. An elevated bleb with IOP that is slightly higher than desired in the early days after surgery is more acceptable than a flat bleb with a low IOP. An inflamed bleb with engorged conjunctival vessels<sup>36</sup> or extensive subconjunctival hemorrhage bodes warnings of subconjunctival fibrosis that may progress rapidly if no intervention is made in the first days after surgery (Fig. 10.29.7). Frequent examinations of the patient are required for observation of the bleb so that the appropriate modality can be employed to encourage success of the surgery. The desired appearance of a bleb is diffuse and elevated, with relatively avascular but not ischemic conjunctiva<sup>37</sup> (Fig. 10.29.8). The ultimate goal is the desired appearance plus lowered IOP to the level that will prevent further glaucoma damage. Individual healing characteristics

**Fig. 10.29.5 Fornix-Based Conjunctival Flap Trabeculectomy.** Needle will pass half-depth through peripheral cornea to begin wing suture to attach conjunctiva. For conjunctival closure, see Video 10.29.2.

**Fig. 10.29.6** View through Hoskins lens after scleral flap suture has been lysed with a laser.

vary tremendously and the surgery is at risk if features that portend failure develop and yet go unrecognized or untreated.

For all patients, the following medications are suggested:

- Topical corticosteroids 6–8 times a day, with gradual taper over 3 months
- Topical cycloplegic drugs for patients with phakia, angle-closure, hypotony
- Topical antibiotics for 1–2 weeks

TABLE 10.29.5 Early Postoperative Manipulations	
Observation	Intervention
Low Bleb, High or Moderate IOP	
Determine level of obstruction	
Most common:	
Tight scleral flap	Release scleral flap suture—laser or releasable (Fig. 10.29.6)
Subconjunctival fibrosis	5-FU injections <sup>a</sup>
Episcleral fibrosis just around scleral flap	Needling with 5-FU, at 4–6 weeks postoperatively
Uncommon:	
Internal sclerostomy obstruction: iris	Laser to release
Internal sclerostomy obstruction: blood	Time, massage, or tissue plasminogen activator intracamerally
Low Bleb, Low IOP	
Leak at incision or in bleb substance	Bandage contact lens or suture in office or operating room
Hypotony caused by uveitis, low aqueous production	Time, topical corticosteroids
Choroidal effusions	Time, cycloplegia, topical corticosteroids, anterior chamber reformation with viscoelastic, drainage, if necessary
Rare:	
Cyclodialysis cleft	Cycloplegia, time, consider repair
Retinal detachment	Repair
High Bleb, Low IOP	
Overfiltration	Time. Watch for increasing choroidal effusions or hypotony maculopathy. May need revision if decreased vision persists
High Bleb, High IOP	
Encapsulation or “Tenon’s cyst”	Time, glaucoma meds, needling with 5-FU, if necessary
Engorged conjunctival vessels	Consider 5-FU injection <sup>a</sup>
HypHEMA	Time, 5-FU injection <sup>a</sup> if bleb is low or inflamed
Fibrin	Increase topical corticosteroids, subconjunctival corticosteroid, 5-FU injection <sup>a</sup>
Early encapsulation before increased IOP	Digital massage
5-FU, 5-fluorouracil; IOP, intraocular pressure. <sup>a</sup> For subconjunctival injection of 5FU, see Video 10.29.3. (Sources: Van Buskirk <sup>10</sup> ; Shingleton <sup>35</sup> )	

See clip: 10.29.3

**Fig. 10.29.7** Early postoperative trabeculectomy with marked vascularity and tortuous vessels.

**Fig. 10.29.8** Two examples of a diffuse, elevated, noninflamed, nonischemic bleb.

Follow-up visits should be made on day 1 following surgery, then weekly for the first 3 weeks, and then typically every other week for an additional 2 months.

## CONCLUSIONS

Trabeculectomy is an effective surgical procedure for managing glaucoma. Attention to detail preoperatively, intraoperatively, and postoperatively provides the best opportunity to tailor the procedure for individual cases and provide the appropriate care.

Changes in surgical technique that could make the surgery safer in the future include the use of glues to seal the conjunctival incision or bleb leaks, as well as the development of agents that provide effective long-term inhibition of subconjunctival fibrosis or are able to reverse hypotony.

Although trabeculectomy techniques have evolved over the last half century, it remains a variation on filtration surgery performed for over 100 years. Trabeculectomy surgical techniques and nuances of postoperative interventions will continue to be refined until such time that we are able to protect the retinal ganglion cells with other measures or procedures that make a bleb-associated fistulizing surgery obsolete.

# Antifibrotic Agents in Glaucoma Surgery

10.30

*Peng Tee Khaw, Richard M.H. Lee, Cynthia Yu-Wai-Man, Jonathan C.K. Clarke, Alastair J. Lockwood*

**Definition:** Medical adjunctive agents and associated surgical techniques used intraoperatively and/or postoperatively to modulate the wound healing associated with glaucoma surgery in an effort to increase its success.

## Key Features

- Mitomycin C.
- 5-fluorouracil.
- Topical intraoperative use.
- Subconjunctival postoperative use.

## Associated Features

- Most commonly indicated for patients with elevated risk of failure, including previous surgery, neovascular glaucoma, black African descent.
- May increase the incidence of hypotony.
- May increase the rate of bleb-associated complications, including endophthalmitis.
- Simple changes in application and surgical technique markedly reduce bleb-related and other complications.

## INTRODUCTION

The use of antimetabolites with safe application of improved surgical techniques represents one of the major advances in the surgical management of glaucoma over the past 20 years. Antimetabolites help prevent scarring after glaucoma filtration surgery. They were used in only the highest-risk patients in the 1980s, but a more recent survey revealed that mitomycin C (MMC) is used in 84% of all patients undergoing primary trabeculectomy by university-based glaucoma physicians in the United States.<sup>1</sup> Studies have shown that a target intraocular pressure (IOP) at the lower end of the normal range (around 12 mm Hg) is required to arrest glaucomatous progression over a decade.<sup>2,3</sup> The concept that the healing response should be modulated to achieve such a target IOP after all surgery has become the new paradigm. The healing response is the major determinant of long-term IOP levels after glaucoma surgery, and prospective studies have demonstrated that the use of antimetabolites improves trabeculectomy survival outcomes.<sup>4,5</sup> Studies of more recent microincisional glaucoma surgery (MIGS) devices that drain into the subconjunctival space have also demonstrated the need to apply antimetabolites to prevent fibrosis and sustain the presence of the postoperative bleb.<sup>6</sup> Modulation of this healing response, together with meticulous surgical techniques, may enable the surgeon to set IOP at the lowest level while avoiding the complications that can be associated with antimetabolites.

## TYPES OF ANTIFIBROTIC AGENTS

The majority of attention has been focused on antimetabolites, such as 5-fluorouracil (5-FU) and MMC. However, other strategies exist to prevent fibrosis and scarring after glaucoma filtration surgery (summarized in Table 10.30.1). Many of the agents listed in Table 10.30.1 have multiple actions on the healing cascade. Other agents, such as corticosteroids, are

used as adjuncts to antimetabolites and are typically used over a longer period.<sup>7</sup> Intraoperative beta irradiation (1000 cGy) by a strontium-90 probe may be similar to a single-dose intraoperative 5-FU application<sup>8,9</sup> or lower dose MMC or at times even stronger.<sup>10</sup> A randomized trial of 320 patients with open-angle glaucoma, who were of black African descent, found the estimated risk of failure of trabeculectomy at 1 year to be 5% in the irradiated arm compared with 30% in the placebo group. The incidence of cataract at 2 years in the irradiated arm, however, was significantly greater.<sup>11</sup> More recently, several antagonists to growth factors are being tested in clinical practice. The antifibrotic agents used most commonly at present are discussed in this chapter.

## INDICATIONS FOR ANTIMETABOLITE USE

Certain patient characteristics increase the risk of scarring and failure after glaucoma surgery, as summarized in Table 10.30.2. However, the risk may still vary within subgroups. More than one risk factor, although each may be categorized as low risk individually, overall may result in placing the patient in a higher risk category. Furthermore, there may be hidden risk factors for failure in what were previously regarded as low-risk “first time surgery” groups. There are recognized changes after chronic topical treatment.<sup>12</sup> Fibroblasts appear to be activated in Tenon’s capsule in patients with open-angle glaucoma. It is not conclusive, however, that this is caused by the drops and not the disease.<sup>13</sup> The extent to which topical treatment might affect patient outcomes after surgery is not fully understood, but there appears to be a clearer correlation with inflammation and fibrotic failure.<sup>14,15</sup> The use of antifibrotic agents after tube drainage surgery has not been conclusively proven, and studies on the use of antifibrotics with newer surgical devices are still ongoing.

## Patient Groups With a High Risk of Scarring

Patient characteristics associated with a high risk of surgical failure include previous failed trabeculectomies, previous cataract surgery through a conjunctival incision, neovascular glaucoma, inflammatory eye disease, aphakia, neovascular glaucoma, black African ancestry, recent intraocular surgery, young age, and chronic topical medication.<sup>16</sup> Most glaucoma specialists agree that patients with any of these should have some form of antimetabolite treatment.

The most definitive study of 5-FU injections in high-risk patients was the randomized, prospective National Eye Institute 5-Fluorouracil Filtration Surgery Study, which showed a 51% failure rate after filtration surgery in patients who had failed trabeculectomy previously or in those who had undergone cataract surgery with a conjunctival incision. In the group that received 5-FU 5 mg injections (twice a day for days 1–7, once a day for days 8–14, total 21 injections), the failure rate was 51% compared with 74% in the placebo group after 5 years.<sup>4</sup> Since then, randomized studies undertaken to compare intraoperative MMC application (0.4–0.5 mg/mL) with 5-FU injections<sup>17–19</sup> have suggested that in high-risk patients, a single application of MMC provides superior long-term pressure control compared with injections of 5-FU without the risk of keratopathy. Corneal epithelial complications are much more common with injectable 5-FU, but both groups had thin avascular blebs, these being more prominent in the MMC-treated groups. A comparative 3-year study of West African patients found fewer postoperative hypotensive medications were required for the MMC-treated group (0.5 mg/mL for 3 minutes) compared with those who received 5-FU application (50 mg/mL for 5 minutes), although with a total of 68 patients, a statistical difference in success was not reached.<sup>20</sup>

TABLE 10.30.1 Wound Healing and Possible Modification After Glaucoma Surgery

Event	Potential Modulation
Previously damaged conjunctiva	Stop medical therapy especially those causing very red eye, if possible
"Preactivated" cells	Preoperative corticosteroids for 1–2 weeks (may not be possible if pressure responder)
Conjunctival/episcleral/scleral incisions	Minimal trauma
Damage to connective tissue	Less invasive surgical techniques
Release of plasma proteins and blood cells	Hemostasis (vital: blood can reverse mitomycin effects) Use of adrenaline or iopidine drops
Activation of clotting and complement Fibrin/fibronectin/blood cell clot	Agents preventing/removing fibrin—e.g., heparin, tissue plasminogen activator (although breakdown products may be fibrogenic)
Aqueous released from eye Some breakdown of blood–aqueous barrier	Blood–aqueous barrier stabilizing agents (e.g., corticosteroids)
Release of growth factors into aqueous	Nonsteroidal anti-inflammatory agents Growth factor antagonists e.g., bevacizumab
Aqueous begins to flow through wound	
Migration and proliferation of polymorphonuclear neutrophil cells, macrophages, and lymphocytes	Anti-inflammatory agents (e.g., corticosteroids/cyclosporine) TNF- $\alpha$ inhibitors (e.g. infliximab) Including systemic immunosuppression. Analogues to serum amyloid P (e.g., PRM-151) inhibit conversion of circulating monocytes into fibroblasts and profibrotic macrophages
	Antimetabolites (e.g., 5-FU/MMC)
Activation, migration, and proliferation of fibroblasts	Preoperative corticosteroids to reduce activation Antimetabolites MMC, 5-FU (MRTF/SRF pathway inhibitors) Rho kinase (ROCK) inhibitors (Possibly local anesthetics which inhibit fibroblasts)
Wound contraction	Anticontraction agents (e.g., colchicine, taxol) MMP inhibitors
Fibroblast synthesis of tropocollagen	MMC, 5-FU, IFN- $\alpha$
Glycosaminoglycans and fibronectin	MMC, 5-FU, MMP inhibitors
Collagen cross-linking and modification	Anti-cross-linking agents (e.g., beta-aminopropionitrile/penicillamine)
Blood vessel endothelial migration and proliferation and blood vessel leakage	Inhibitors of angiogenesis and blood vessel leakage (e.g., bevacizumab and ranibizumab, angiostatin)
Resolution of healing	MMC, 5-FU
Apoptosis	Death receptor ligands
Disappearance of fibroblasts	Stimulants of apoptosis pathways
Fibrous subconjunctival scar	
Anti-inflammatory Inhibits production and activity of TGF- $\beta$	Pirfenidone in idiopathic pulmonary fibrosis
Events and agents have overlapping time duration and action. 5-FU, 5-fluorouracil; IFN, interferon; MMC, mitomycin C; MMP, matrix metalloproteinase; MRTF/SRF, myocardin-related transcription factor/serum response factor; TNF- $\alpha$ , tumor necrosis factor-alpha.	

Using a single intraoperative 5-FU application, Egbert et al.<sup>21</sup> carried out a randomized prospective study in a group of West African patients who had a high risk of failure. They showed success rates of 83% in the 5-FU-treated group versus 39% in the control group, with a mean follow-up of 282 days.

The intraoperative MMC regimen, rather than postoperative subconjunctival 5-FU injections, has become the treatment of choice for high-risk patients. There is increased efficacy, ease of application, and virtual absence of corneal side effects. However, longer periods of follow-up are needed to monitor the development of bleb leaks, hypotony, and endophthalmitis, in view of the thinner and highly avascular blebs seen with MMC. The incidence of these so-called high-risk blebs has been dramatically reduced, however, because of the introduction of a theory of cystic bleb formation, that changed the method of antimetabolite application during glaucoma surgery.<sup>22–25</sup> Systemic corticosteroids and immunosuppressants are used in particular high-risk groups but are not routine and can have severe side effects if used by an inexperienced physician.<sup>26</sup>

Patient Groups With an Intermediate or Low Risk of Scarring

In patients with no previous ocular surgery and no significant comorbidity apart from glaucoma, the use of antimetabolites is more controversial. Intraoperative MMC application not only increases the success rate of surgery but also increases the incidence of hypotony.<sup>27</sup> Bindlish et al. reported an incidence of late hypotony (IOP <6 mm Hg) in 42% of eyes at some point between 6 months and final follow-up at 5 years, in a series of 123 primary trabeculectomies with MMC.<sup>28</sup> Hypotony occurs more in younger patients, particularly those who have myopia with thin sclera.<sup>27,29</sup>

5-FU injections have been used in lower-risk groups, which include those who have undergone first-time filtration surgery,<sup>30</sup> young patients,<sup>27</sup> and those with normal-tension glaucoma,<sup>31</sup> to achieve lower IOPs and

superior success rates. Complications, such as corneal epithelial changes, are more common but generally only in the short term.<sup>30</sup> Cell culture experiments suggest that a single 5-minute application of 5-FU is able to inhibit fibroblasts for several weeks without severe long-term damage and be equivalent to low-dose 5-FU injections.<sup>32,33</sup> Several studies using single applications of intraoperative 5-FU with short-term follow-up have reported promising results in low-risk patients. Lanigan et al.<sup>34</sup> reported a success rate of 77% in high-risk patients (those with neovascularization, previous failed filtration surgery, aphakia, uveitis, or multiple risk factors), with a 100% success rate in the low-risk groups. Feldman et al.<sup>35</sup> reported an overall success rate of 85% in high-risk patients and a success rate of 92.9% in low-risk patients; no hypotony was seen in the Feldman study. However, both studies were of short duration and had no controls. Therefore, failure occurs in higher-risk patients who have a prolonged or aggressive healing response, but in lower-risk patients the success rate is very good (>90%) with no clinically significant hypotony. An improvement in survival was also found for patients in East Africa with a single 5-minute application of low dose 5-FU (25 mg/mL), interestingly with a much lower failure rate in the control group<sup>36</sup> compared with patients in West Africa.<sup>21</sup> There is evidence that 5-FU trabeculectomy maintains IOP in the low teens compared with nonaugmented surgery.<sup>37,38</sup>

Comparative studies for primary trabeculectomy have not found one antimetabolite to be clearly superior to another. A trial of 5-FU 50 mg/mL versus MMC 0.2 mg/mL in first-time trabeculectomy (low risk) in the United States did not show any statistically significant differences, to date, in efficacy or side effects of 115 eyes randomized to receive either treatment.<sup>39</sup> These findings were similar to those of WuDunn et al.,<sup>40</sup> who used the same doses of 5-FU and MMC.

A single antimetabolite regimen may not be adequate for all patients. The type and dose of drugs needs to be titrated depending on the individual patient's risk factors and healing response. The authors use a "titratable" regimen that is based on laboratory<sup>33</sup> and clinical data gained from experience using the different single-application agents and concentrations

TABLE 10.30.2 Risk Factors for Scarring After Glaucoma Filtration Surgery

Risk Factors	Risk (+ to + + +)	Comments
<b>Ocular</b>		
Neovascular glaucoma (active)	+ + +	May require panretinal photocoagulation ± anti-VEGF
Previous failed filtration surgery	+ + (+)	Consider tube surgery
Previous conjunctival surgery	+ +	Uncertain
Chronic conjunctival inflammation	+ + (+)	
Previous cataract extraction (conjunctival incision)	+ + (+)	
Aphakia (intracapsular extraction)	+ + +	
Previous intraocular surgery	+ +	Depends on type of surgery
Uveitis (active, persistent)	+ +	
A red, injected eye	+ +	
Previous topical medications (Beta-blockers + pilocarpine)	+ (+)	Particularly if they cause a red eye
(Beta-blockers + pilocarpine + adrenaline)	+ + +	
New topical medications	+ (+)	
High preoperative intraocular pressure (higher with each 10 mm Hg rise)	+ (+)	
Time since last surgery	+	
(especially if within last 30 days)	+ + (+)	
Inferiorly located trabeculectomy	+	Increased risk of endophthalmitis
<b>Patient</b>		
African-Caribbean descent	+ +	
West African descent	+ + (+)	
East African descent	+	
Indian subcontinent descent	+	
Hispanic descent	(+)	
Japanese descent	(+)	
Older adult (over 60 years)	(+)	
Adolescent/younger adult (16–40 years)	+ (+)	
Children (under 16 years)	+ +	

VEGF, Vascular endothelial growth factor.

(the authors call this the *Moorfields/Florida regimen* [“More Flow regimen”]). This regimen evolves constantly, but the present one is summarized in [Box 10.30.1](#). Postoperative, subconjunctival injections of 5-FU may be used in addition to the application of intraoperative antimetabolites.

APPLICATION TECHNIQUES

There are great variations in technique used to deliver intraoperative antimetabolites, which may account for some of the published variations in efficacy and complications. It is important for individual surgeons to maintain a consistent technique and to periodically re-evaluate their experience in the use of this technique. Intraoperative MMC applications are commonly used, but preoperative MMC injections are also now used prior to glaucoma filtration surgery.<sup>41</sup> It is now better understood how antimetabolites, particularly MMC, work in vivo causing long-term tissue cell death and growth arrest.<sup>33</sup> There is remnant functional activity in peripheral fibroblasts, which form a ring of scar tissue around the bleb (“ring of steel”).<sup>42</sup> This has allowed the development of strategies in antimetabolite delivery and associated surgical techniques, which increase safety and improve bleb appearance dramatically ([Fig. 10.30.1](#)). Optimization of the application technique is important for refinement and long-term IOP control of MIGS devices that drain into the subconjunctival space (the “R1R2” principle, where R1 is the outflow resistance due to the device and R2 is the outflow resistance caused by the bleb).

This change has led to a reduction in the number of cystic blebs from 90% to 29% and has reduced bleb-related complications, particularly endophthalmitis, from 15% to 0% over a 3-year follow-up period ([Fig. 10.30.2](#)).<sup>25</sup> More recent reports of this safer trabeculectomy technique have recorded a success rate of 96.7% (IOP <21 mm Hg) at 3 years in a complex case mix,<sup>43</sup> and Stalmans et al. reported a success rate of 100% (IOP <21 mm Hg) in lower-risk patients at 15.7 months mean follow-up with few complications (flat anterior chamber 1.8%; hypotony beyond 3 weeks 1.5%).<sup>44</sup> Simple

STRATEGIES IN ANTIMETABOLITE DELIVERY AND ASSOCIATED SURGICAL TECHNIQUES

Fig. 10.30.1 Strategies in antimetabolite delivery and associated surgical techniques that increase safety and improve bleb appearance dramatically.

BOX 10.30.1 Moorfields Eye Hospital/University of Florida (More Flow) Regimen

Low-Risk Patients (Nothing or 5-FU 50 mg/mL 5 min)<sup>a</sup>

- No risk factors
- Short-term topical medication
- Older adults

Intermediate-Risk Patients (5-FU 50 mg/mL 5 min or MMC 0.2 mg/mL 3 min)<sup>a</sup>

- Chronic topical medications or others that cause a red eye
- Previous cataract surgery without conjunctival incision (capsule intact)
- Several low-risk factors
- Combined glaucoma filtration surgery/cataract extraction
- Previous conjunctival surgery (e.g., squint/detachment surgery)
- East African ancestry

High-Risk Patients (MMC 0.5 mg/mL 3 min) (Consider Tube Implantation)

- Neovascular glaucoma (combine with bevacizumab)
- Chronic persistent uveitis (anti-inflammatory/immunosuppression)
- Previous failed trabeculectomy/tubes with or without antimetabolites
- Chronic conjunctival inflammation
- Cicatricial conjunctival disease
- Multiple risk factors
- Aphakic glaucoma (a tube with antimetabolites may be more appropriate in many of these cases)
- West African ancestry

An intraoperative, single-dose regimen for scarring after glaucoma filtration surgery. (This regimen is still evolving.) Other factors may also determine the choice of agent, such as the need for a low target pressure resulting from advanced disease (require a stronger antimetabolite treatment). Beta-radiation 10Gy can also be used.

Postoperative 5-FU injections can be given in addition to the intraoperative applications of antimetabolite.

5-FU, 5-fluorouracil; MMC, mitomycin C.

adjustments of technique should result in much lower complication rates for many thousands of patients (summarized in [Box 10.30.2](#)).

Type and Concentration of Intraoperative Agent and Time of Exposure

The optimal concentration of intraoperative MMC has not been established.<sup>45</sup> Chen et al.<sup>46</sup> reported results in high-risk patients since 1981

**Fig. 10.30.2** Focal cystic bleb prone to leakage, infection, and dysesthesia in the left eye (limbus-based conjunctival flap, small scleral flap, and smaller area of mitomycin C [MMC] 0.4 mg/mL treatment). Diffuse noncystic bleb appearance in right eye of the same patient (fornix-based flap, larger scleral flap, and larger area of MMC 0.5 mg/mL treatment).

### BOX 10.30.2 Improvements in the Use of Intraoperative Antimetabolites

- Use of weaker agents (intraoperative 5-FU), lower concentrations of MMC for lower-risk individuals or individual at high risk of hypotony or other complications of antimetabolites
- Nonfragmenting sponges (polyvinyl alcohol rather than methylcellulose)
- Protection of cut edge with special clamp (John Weiss or Duckworth and Kent, UK) to prevent dehiscence
- Treatment under both scleral flap and conjunctival flap. The use of the sponge both under the scleral flap and the conjunctiva does seem to enhance the success rate
- Measures to secure scleral flap—smaller sclerostomy, larger scleral flaps, multiple tight sutures that are both adjustable (adjustable suture control [ASC]) and releasable
- Intraoperative flow control—continuous positive pressure infusion giving accurate indication of flow, maintaining blood–aqueous barrier and washing out cytokines
- Measures to produce diffuse noncystic blebs—large scleral flaps, fornix-based conjunctival flap, or extremely posterior limbus-based incision and large surface area of antimetabolite treatment; **big** (treatment area, scleral flap) and **backward** (aqueous flow direction) is better for blebs

without failures but a 66% rate of hypotony with MMC 0.4 mg/mL, a 22% failure rate with no hypotony with MMC 0.2 mg/mL, and a 37% failure rate with no hypotony with MMC 0.1 mg/mL. In a randomized, prospective study of Japanese patients given primary surgery, Kitazawa et al.<sup>47</sup> had a 100% success rate with MMC 0.2 mg/mL (but transient hypotony maculopathy and cataract progression in 18%) and a 64% success rate with MMC 0.02 mg/mL with no hypotony or cataract progression. For intraoperative 5-FU, both 50 mg/mL and the weaker 25 mg/mL have been used, but no direct comparison has been made between the two.

The optimal time of exposure has also not been determined. Megevan et al. retrospectively compared eyes treated with MMC 0.2 mg/mL for 2 minutes or 5 minutes.<sup>48</sup> There was no statistically significant difference in success rate or complications, but hypotony and endophthalmitis still occurred. In another study MMC was administered intraoperatively at 0.5 mg/mL for 5 minutes or 0.4 mg/mL for 3 minutes in Indian patients.<sup>49</sup> No significant difference occurred in postoperative IOP, hypotony, or postoperative filtration failure rate. However, the group treated with the higher concentration for 5 minutes had a higher incidence of serous choroidal detachment. One patient from each group developed postoperative endophthalmitis during the study period. Shorter applications of 2–3 minutes, compared with 5 minutes, appear to have the same efficacy, but if applications are shortened to less than 2 minutes, suboptimal cellular and tissue absorption may occur. In a study of 5-FU uptake in tissues, the concentrations reached a plateau at 3 minutes.<sup>50</sup> Even shorter application times may result in greater variations in drug delivery.

Changes in the concentration of the agent are more likely to give reproducibly titratable effects compared with variations in exposure time. Therefore, to achieve consistent and predictable results, it is probably

**Fig. 10.30.3** Diagrammatic illustration of the “cystic bleb” hypothesis requirements for cystic bleb formation with or without antimetabolites. Blue arrows indicate anterior aqueous flow; light blue line and green dots indicate a ring of scar tissue, the so-called ring of steel.

more important that the individual surgeon becomes accustomed to one or two concentrations and one exposure time. The authors use MMC 0.2 or 0.5 mg/mL and 3 minutes, on the basis of our previous studies.

### Type of Sponge

Small variations in technique may have profound effects on the clinical result and complications. The type of sponge may affect significantly the amount of drug delivered. Chen et al.<sup>46</sup> originally used a Gelfoam sponge, but most clinicians use commercially available sponges (e.g., Weck cell, Merocel), which have different retention and drug-releasing capabilities and which may be cut to different sizes. Attempts to standardize the dose of drug delivered have been made,<sup>51</sup> and the accurate application of MMC drops to a standard sponge will deliver a known dose. The authors currently use polyvinyl alcohol sponges (Merocel, Mystic, CT) as these do not disintegrate like methylcellulose and leave fragments in the wound that can cause significant foreign body granulomas.<sup>52</sup> A formulation and kit licensed by the U.S. Food and Drug Administration is now available (Mobius Therapeutics, St. Louis, MO).

### Larger Areas of Antimetabolite Treatment

On the basis of clinical observation, a hypothesis as to why cystic blebs occur has been put forward (Fig. 10.30.3). By treating larger areas, bleb-related complications can be reduced.<sup>25</sup> This clinical finding has been confirmed experimentally.<sup>53</sup> A specially designed clamp (2-686; Duckworth & Kent, Baldock, UK) for use during either limbal or fornix-based surgery helps protect the conjunctival edge from exposure (Fig. 10.30.4).

Treatment under both the scleral flap and conjunctival flap, particularly in high-risk cases, can be considered.<sup>54</sup> Finally, staining of the antimetabolites with trypan blue has been described permitting the delineation of the treatment area.<sup>55</sup> This principle has been adopted very successfully for current devices with good success rates and diffuse noncystic blebs.<sup>6</sup>

### POSITION OF DRAINAGE AREA UNDER EYELID

The positioning of the scleral flap and treated area is often neglected but is extremely important. Interpalpebral and inferiorly placed blebs have a high incidence of endophthalmitis, particularly in association with antimetabolites.<sup>56,57</sup> In addition, it is important to assess the lid position preoperatively and to try to place the bleb at the point of maximum coverage of the lid. If no space exists for a superior trabeculectomy with antimetabolite, better alternative methods may include tube drainage devices or cyclodestructive procedures.

### CLOSURE OF SCLERAL FLAP AND ASSOCIATED SURGICAL TECHNIQUES

Healing at the cut edge of conjunctiva may be markedly inhibited by antimetabolites, and hypotony is prevented primarily by the resistance afforded

**Fig. 10.30.4 Intraoperative Antimetabolite Being Applied.** The cut edge of conjunctiva is protected by a special clamp (Duckworth and Kent) during surgery. As large an area as possible is treated to achieve a diffuse noncystic bleb.

**Fig. 10.30.5 Adjustable Suture Control.** Sutures being adjusted through the conjunctiva with duck-billed forceps to ensure gradual lowering of intraocular pressure after antimetabolite use.

by the scleral flap. Therefore, this flap has to be sufficiently thick and wide relative to the sclerostomy to provide this resistance, and it has to be sutured adequately enough to achieve this resistance and yet be adjustable gradually. This adjustability is achieved by laser suture lysis, or adjustable/releasable sutures, although too early a release of sutures may be associated with long-term hypotony.<sup>27</sup> When antimetabolites (particularly MMC) are used, suture lysis (even several months after surgery) may result in hypotony.<sup>58</sup> This also applies to occluding sutures left within or around the tube lumen after tube implant surgery.

Late choroidal effusions and hemorrhage after suture removal have been reported, even many months after the surgery.<sup>59</sup> With MMC, sutures should be released late. In particular, the adjustable/releasable suture(s) should be tied tighter, but IOP should be checked in patients who have marked visual field loss in the first few hours after surgery. If the pressure is raised on the first postoperative day, then gentle pressure is applied to the back of the scleral flap, which very slightly loosens the flap, allowing outflow of aqueous, and lowers the opening pressure without the complete loss of tension that occurs when sutures are released. Alternatively, a technique of adjustable sutures can be used in which a special pair of highly polished forceps (Khaw forceps 2-502; Duckworth & Kent, Baldock, UK) can be used transconjunctivally to adjust the sutures and thus the IOP downward gradually until the target pressure is reached (Fig. 10.30.5).<sup>60</sup> Results of a subsequent study suggest that suture adjustment may be superior to both posterior lip massage and releasable sutures for managing IOP in the early phase following glaucoma surgery.<sup>61</sup> Manipulation of the scleral flap and associated sutures may only lower the IOP for minutes to hours but the effect persists if the suture tension is decreased. Ultimately, optimizing the success of the surgery with antimetabolites is dependent on a combination of simple technical modifications, which the authors have termed the *Moorfields Safer Surgery System*.<sup>60</sup>

## POSTOPERATIVE INJECTIONS

Subconjunctival injections of 5-FU may be used postoperatively on their own or in combination with intraoperative MMC or 5-FU, if the pressure rises and the healing response is still marked. A meta-analysis suggested that three injections or fewer may have no impact on long-term success and only five injections or more may be effective if no antimetabolite is used intraoperatively.<sup>62</sup>

The technique of injection has evolved. The 5-Fluorouracil Filtration Surgery Study regimen was 5-FU 5 mg in a volume of 0.5 mL given 180° from the filtration site (current practice is summarized in Box 10.30.3). On the basis of pharmacokinetic studies, the authors also sometimes use a subconjunctival viscoelastic injection (Healon GV, Pharmacia, NJ) and then inject the 5-FU on the far side of the viscoelastic, which prevents any 5-FU reflux into the tear film (Fig. 10.30.6). This also lengthens the duration of action. Corneal side effects are very rare with this regimen.

Subconjunctival injections of MMC have been advocated and described increasingly, particularly with procedures, such as needling,<sup>62-65</sup> and there

**Fig. 10.30.6** Viscoelastic wall to prolong duration and minimize side effects of subconjunctival 5-fluorouracil.

### BOX 10.30.3 Improvements in Injectable 5-Fluorouracil

- Reduction in number of injections given
- Injections given closer to bleb area—increased efficacy for same dose
- Long injection track—reduction in epitheliopathy
- Use of small-bore needle (e.g., 30-gauge)
- Injection of viscoelastic—prolonged release and no corneal side-effects
- Use in conjunction with intraoperative antimetabolites—reduced need for injections

is some evidence that it may be superior to subconjunctival 5-FU. Although successful needling revisions of blebs have been reported above using subconjunctival injections of smaller volumes (0.01 mL at 0.2–0.4 mg/mL), the potential risks of subconjunctival MMC are significant. Given the cytotoxicity of MMC, this should be used with great caution.

## COMPLICATIONS

Many complications of filtration surgery have been described, and the use of antimetabolites increases the incidence of some of these. In particular, short-term and long-term hypotony associated with maculopathy (which

**BOX 10.30.4 Potential Complications of Antimetabolites****Hypotony**

- Particularly if scleral flap not adequately closed or high-dose MMC used

**Prevention**

- Close scleral flap securely—releasable sutures are very useful. May require multiple sutures, particularly if MMC used
- Do not make scleral flap too small or thin, otherwise outflow cannot be adequately restricted
- Delayed suture release—if MMC used suture release even months after surgery may result in hypotony
- Adjustable suture control (ASC)—gradual loosening of sutures down to target pressures

**Complications of Hypotony**

- Including maculopathy, which may be irreversible even after pressure is restored, choroidal effusions and bleeding, cataract and phthisis

**Prevention**

- Caution when using strong antimetabolites in high-risk patients, for example, those with myopia who appear more prone to get hypotony-associated problems, such as maculopathy (soft sclera)
- Intraoperative infusion (Lewicky cannula) to gauge outflow; do not finish until flow secured
- Low threshold to resuture; use intraocular viscoelastic as a temporizing measure

**Wound Edge Leaks****Prevention**

- Identify patients at risk of poor wound healing (e.g., vitamin deficiencies or alcohol dependence)
- Small conjunctival incision and minimal tissue handling
- Ensure wound is securely closed, vascular needle prevents buttonholing
- Mattress sutures if fornix-based flap—test at end of surgery to ensure watertight
- Protect cut edge of conjunctiva from drug (e.g., special clamp)

**Epithelial Erosions**

- Mainly with injected 5-FU, which leaks into tear film

**Prevention**

- Use intraoperative sponge technique
- Use long injection track for injections to prevent tear film reflux and washout by tears after injection

5-FU, 5-fluorouracil; MMC, mitomycin C.

- Use viscoelastic to prevent tear film reflux in susceptible patient (e.g., surface problems)

**Intraocular Penetration and Damage**

- Intraocular damage can include endothelial damage and ciliary body destruction—possibly with high-concentration MMC (controversial)

**Prevention**

- Treat with antimetabolite sponge and washout before making scleral incision
- Great care when injecting 5-FU subconjunctivally close to the bleb, particularly in a soft eye
- High risk if MMC is injected

**Infection—Blebitis and Endophthalmitis, Bleb Breakdown and Leakage****Prevention**

- Identify patients at risk (e.g. meibomian disease)
- Avoid overtreating—use appropriate antimetabolite for patient
- Use large surface area treatment and large scleral flap—radically reduces incidence of cystic blebs prone to infection and leakage
- Avoid thin scleral flaps
- Avoid interpalpebral or inferiorly sited blebs—infection rate may be 5–10 times higher than bleb under upper lid

**Scleritis**

- Occurs particularly with interpalpebral/inferior blebs

**Prevention**

- Avoid interpalpebral and inferior blebs
- Minimize strength of antimetabolite

**Scleromalacia/Thinning/Necrosis****Prevention**

- Avoid areas of scleral thinning—theoretical possibility

**Malignancy/Teratogenicity/Long-Term Cumulative Effects****Prevention**

- Continued surveillance—on both patient and medical staff
- Careful handling and disposal of cytotoxics required
- Avoid using if any chance of pregnancy in patient
- Potentially more long-term complications with mitomycin C than with 5-fluorouracil

may be irreversible), choroidal effusions, or hemorrhage may occur with an increased incidence. The other major concern is the potentially high long-term incidence of endophthalmitis, especially with avascular cystic blebs, seen particularly with the use of higher concentrations of MMC. Using the appropriate surgical techniques can considerably reduce the risk of these complications. A list of major potential complications and possible ways to prevent some of these are presented in [Box 10.30.4](#).

**FUTURE STRATEGIES TO PREVENT FIBROSIS**

Although current agents (particularly MMC) are extremely effective in the prevention of fibrosis, considerable room still exists for improvement. Long-term complications may only become apparent many years later. A key area for the future lies in a better understanding of the cellular and molecular processes involved in the healing processes, and of the exact effects of the various agents used to modulate the process. Biological factors may have profound effects.

A number of novel antifibrotic agents are currently under development and at various stages of nonclinical and clinical trials. The necessity for long periods of follow-up and valid outcome endpoints is a significant challenge. Trabio (anti-transforming growth factor beta [TGF- $\beta$ ] antibody) was shown to be effective in reducing scarring in vivo<sup>66</sup> and in pilot human studies<sup>67</sup> with relatively diffuse noncystic blebs. However, the dose used in the later trial based on initial studies<sup>66</sup> may have been wrong, and long-term prolonged dosing as shown in the subsequent study by Mead et al. may be necessary.<sup>68</sup> Serum amyloid P (human pentraxin-2) is a serum protein that inhibits the transformation of circulating monocytes into fibrocytes and the activation of macrophages involved in fibrosis.<sup>69,70</sup> A recombinant form

(PRM-151) has been shown to inhibit myofibroblast generation in rabbit corneas,<sup>71</sup> and a phase II trial in the form of a series of conjunctival injections after trabeculectomy has been completed.

Vascular endothelial growth factor (VEGF) antibody therapy has recently exhibited considerable potential in the modulation of wound healing for glaucoma filtration surgery. VEGF is both stimulatory to endothelial cells in blood vessel development<sup>72</sup> and is upregulated in fibroblasts in tissue where scarring is active.<sup>73</sup> The inhibition of VEGF has been shown to reduce scar tissue deposition in cutaneous wounds in the mouse.<sup>74</sup> VEGF is upregulated in the aqueous after glaucoma filtration surgery and can stimulate Tenon's fibroblast proliferation. Furthermore, in the rabbit, an aggressive scarring animal model of glaucoma filtration surgery, bevacizumab injections can promote bleb survival.<sup>75</sup> When compared with 5-FU in this model, bevacizumab-injected blebs resulted in a better bleb morphology and prolonged survival.<sup>76</sup> Combining 5-FU and bevacizumab also appears to work in a synergistic way.<sup>77</sup> Evidence in humans that anti-VEGF antibodies could modulate conjunctival scarring after glaucoma filtration surgery came initially from a report of a successful bleb needling procedure using bevacizumab.<sup>78</sup> Grewal et al.<sup>79</sup> performed a prospective case series of trabeculectomies for open-angle glaucoma patients using bevacizumab as an adjunct. Although the numbers were small (12) and the follow-up 6 months, those authors found good control of IOP with no signs of ocular toxicity or adverse effects.<sup>79</sup> Vandewalle et al. also reported that perioperative administration of intracameral bevacizumab significantly reduced the need for needling interventions and led to a higher success rate after trabeculectomy.<sup>80</sup>

Anti-VEGF therapy may be particularly applicable in the treatment of patients undergoing trabeculectomy with neovascular glaucoma. As yet,

there are only reports of individual cases; however, intravitreal injection at the time of surgery has been reported to have resulted in both good control of proliferative disease and IOP and profound regression of iris neovascularization.<sup>81</sup>

Intracellular triggers of fibroblast activity may also be suppressed. Adenoviral *p53* gene transfer leads to a significant growth inhibition of human Tenon's capsule fibroblast *in vivo*.<sup>82</sup> The downstream suppressor protein of *p53* is *p21 WAF-1/Cip-1*. Adenoviral-mediated treatment of an animal glaucoma model demonstrated prevention of wound healing and has potential as a novel treatment option.<sup>83</sup> Human RAD50 (*hRAD50*) is involved in the repair of mammalian DNA, and overexpression has been demonstrated to have antiproliferative activity. *In vitro* studies have demonstrated that histological antiproliferative effects of local *hRAD50* on the conjunctival fibroblasts are similar to those of MMC in an animal model but that damage to the basal lamina and other structures was not seen.<sup>84</sup> Modulation of matrix metalloproteinase activity has also proved to be a very exciting modality of future treatment with results in an experimental model almost equal to MMC without the tissue destruction seen with MMC.<sup>85–87</sup> New modalities of scar reduction, including nanotechnology to produce agents that suppress inflammation, have also been shown to dramatically reduce scar formation after experimental glaucoma surgery.<sup>88</sup>

Ultimately, it is likely that antiscarring agents will be used in all patients, possibly in combination, analogous to the situation in cancer chemotherapy. These combination regimens together with new device and drug release technologies will evolve to give us the safe, prolonged, long-term, maximal lowering of IOP that is associated with minimal or no progression of glaucoma—the Holy Grail of glaucoma treatment.

# Drainage Implants

Kateki Vinod, Steven J. Gedde

10.31

**Definition:** Glaucoma drainage implants are surgically placed to lower intraocular pressure. They may be used at any stage in the treatment of glaucoma.

**Key Feature**

- Glaucoma drainage implants bypass the natural aqueous outflow systems and typically shunt aqueous humor via a silicone tube from the anterior chamber to a plate in the sub-Tenon's or subconjunctival space, generally more than 8 mm posterior to the limbus.

**Associated Features**

- Glaucoma drainage implants may be either valved or open tubes.
- Tube exposure is a major risk factor for endophthalmitis.

**HISTORICAL PERSPECTIVE**

Modern glaucoma drainage implants (GDIs) have evolved from the eponymous device first described by Molteno in 1969.<sup>1</sup> Refinements in implant design and surgical technique have led to the routine use of GDIs in the surgical management of glaucoma. Analysis of Medicare claims data demonstrated a 77% decline in trabeculectomy use in the United States between 1994 and 2012, with a concurrent 410% increase in the number of GDI surgeries.<sup>2</sup> Surveys of the American Glaucoma Society membership have shown a similar shift in surgical practice patterns between 1996 and 2008, with a significant increase in the use of GDIs in various clinical settings.<sup>3-5</sup>

**BASIC CONCEPT**

Drainage implants share a common design consisting of a silicone tube, which is inserted into the eye through a scleral fistula and shunts aqueous humor to an episcleral endplate located in the equatorial region of the globe. Capsule formation around the endplate occurs over a period of 4–6 weeks and provides resistance to aqueous flow. Aqueous pools within the

reservoir created by the capsule diffuses across the bleb wall for eventual reabsorption into the systemic circulation, thereby lowering intraocular pressure (IOP). Thinner blebs with larger surface areas tend to produce lower IOP.

Commercially available GDIs include the Ahmed glaucoma valve (New World Medical, Inc., Rancho Cucamonga, CA), Baerveldt glaucoma implant (Abbott Medical Optics, Inc., Santa Ana, CA), and Molteno glaucoma drainage device (Molteno Ophthalmic, Ltd., Dunedin, New Zealand). These differ in surface area, endplate composition, implant profile, and presence or absence of a valve (Table 10.31.1). Valved devices (i.e., Ahmed implants) house a mechanism that allows aqueous egress above a minimum opening pressure and provide immediate IOP control, whereas nonvalved devices (i.e., Baerveldt and Molteno implants) require ligation to provide temporary restriction to flow while awaiting formation of an adequate capsule.

**INDICATIONS**

Drainage implants were traditionally reserved for eyes with complex, refractory glaucomas with one or more prior failed filtering surgeries or considered at high risk for trabeculectomy failure. Eyes with neovascular glaucoma, uveitic glaucoma, certain childhood glaucomas, iridocorneal endothelial syndrome, or extensive scarring from prior surgery, trauma, or conjunctival cicatrizing disease were among those chosen for primary GDI surgery. The role of GDIs has expanded in recent years, in part as a result of evidence from randomized clinical trials supporting their use in eyes at lower risk of filtration failure (see Evidence from Randomized Clinical Trials).

Glaucoma drainage implant surgery may be performed using a staged approach or in combination with cataract, corneal, and/or vitreoretinal surgery in patients with multiple ocular comorbidities. Drainage implants appear to be less prone to failure than trabeculectomy in eyes requiring subsequent cataract surgery because postoperative inflammation can compromise the longevity of a filtering bleb.<sup>6</sup> Patients who have suffered a bleb-related complication or trabeculectomy failure in one eye may be considered for a primary drainage implant if incisional glaucoma surgery is required in the fellow eye. Although all patients need careful postoperative follow-up after incisional glaucoma surgery, those who are unable or less likely to adhere to the more rigorous postoperative visit schedule required after trabeculectomy may be better candidates for GDI surgery.

TABLE 10.31.1 Features of Commercially Available Glaucoma Drainage Implants

Implant Type	Manufacturer	Model	Single or Double Plate	Surface Area (mm <sup>2</sup> )	Endplate Composition	Implant Profile (mm)	Valve
Ahmed®	New World Medical, Inc. (Rancho Cucamonga, CA)	FP7	Single	184	Silicone	2.1	Present
		FP8 <sup>a</sup>	Single	102	Silicone	2.1	
		S2	Single	184	Polypropylene	1.6	
		S3 <sup>a</sup>	Single	85	Polypropylene	1.6	
Baerveldt®	Abbott Medical Optics, Inc. (Santa Ana, CA)	BG103-250	Single	250	Silicone	0.84	Absent
		BG101-350	Single	350	Silicone	0.84	
		BG102-350 <sup>b</sup>	Single	350	Silicone	0.84	
Molteno®	Molteno Ophthalmic, Ltd. (Dunedin, New Zealand)	GL	Single	230	Polypropylene	1.5	Absent
		GS	Single	175	Polypropylene	1.5	
		SL	Single	245	Polypropylene	0.95	
		SS	Single	185	Polypropylene	0.95	
		R2/L2	Double	274	Polypropylene	1.5	
		DR2/DL2	Double	274	Polypropylene	1.5	
		S1	Single	137	Polypropylene	1.5	

<sup>a</sup>Designed for use in pediatric cases or small eyes.

<sup>b</sup>Includes a 90° Hoffman elbow for pars plana insertion.

Data from <http://www.newworldmedical.com>; <http://www.abbottmedicaloptics.com>; <http://www.molteno.com>.

## PREOPERATIVE CONSIDERATIONS

Assessment of conjunctival mobility at the slit lamp in eyes with previous surgery can help guide quadrant selection for placement of a GDI. Preoperative gonioscopy allows identification of high peripheral anterior synechiae that may impede anterior chamber tube entry through certain portions of the angle. Glaucoma drainage implants are most commonly inserted into the anterior chamber, but a shallow anterior chamber or endothelial cell dysfunction may necessitate sulcus or pars plana placement in patients with pseudo-phakia or aphakia. Sulcus or pars plana placement may also be preferable in pseudo-phakic or aphakic eyes with a corneal graft or those in which future corneal surgery is likely because drainage implants may contribute to graft failure.<sup>7</sup>

Patients in whom pars plana tube placement is planned should undergo thorough pars plana vitrectomy, with particular attention to shaving of the vitreous base in the quadrant of intended tube insertion. Repeat vitrectomy is usually necessary in patients who have been previously vitrectomized to ensure adequate vitreous removal. Combined pars plana vitrectomy and pars plana GDI insertion has been shown to lower IOP successfully in patients with aphakia and pseudo-phakia,<sup>8,9</sup> with an efficacy comparable with that of anterior chamber tube insertion.<sup>10,11</sup> If preoperative examination reveals vitreous in the anterior chamber as a result of prior posterior capsular rupture or zonular dehiscence, then a vitrectomy is indicated prior to or at the time of GDI surgery to minimize the risk of vitreous occlusion of the distal tube tip.<sup>12</sup>

Patients with neovascular glaucoma should be treated preoperatively with panretinal photocoagulation or anti-vascular endothelial growth factor, whenever possible, to minimize the risk of intraoperative bleeding. Use of preoperative intravitreal bevacizumab has been associated with a decreased risk of postoperative hyphema, but it has not demonstrated an effect on postoperative IOP or success rates following GDI surgery.<sup>13–15</sup>

## IMPLANT SELECTION

Valved devices are often selected in patients with severely elevated preoperative IOP who require immediate IOP lowering, such as those with neovascular glaucoma. Patients at high risk for hypotony, including those with uveitis or who have undergone prior cyclodestructive procedures, may also benefit from placement of a valved implant. Evidence from recent clinical trials may further guide the selection of a particular implant type, endplate size, or endplate composition (see [Evidence from Randomized Clinical Trials](#)). Ultimately, the choice of implant depends on the surgeon's comfort and preference, which is determined by his or her experience.

## SURGICAL TECHNIQUE

### Anesthesia

Glaucoma drainage implant surgery is typically performed under monitored anesthesia care with a retrobulbar or peribulbar block to provide local anesthesia. Alternatively, a sub-Tenon's block can be administered after an initial conjunctival peritomy and posterior dissection are performed and may be useful in patients who are monocular or under anticoagulation therapy. General anesthesia is rarely required.

### Quadrant Selection

The superotemporal quadrant is usually chosen for placement of a first GDI because of better surgical exposure and a reduced likelihood of postoperative strabismus. The inferonasal quadrant is generally selected in the presence of an existing superotemporal GDI or extensive conjunctival scarring from prior surgery, trauma, or inflammation. The superonasal quadrant is generally avoided because it is associated with a higher rate of postoperative strabismus and a risk of acquired Brown's syndrome,<sup>16–20</sup> as well as with a theoretical risk of optic nerve impingement with excessively posterior endplate placement in smaller eyes.<sup>21,22</sup> Use of the inferotemporal quadrant is less common because of the presence of the inferior oblique muscle<sup>22</sup> but may be required in eyes in which the superotemporal and inferonasal quadrants are not available because of conjunctival scarring or scleral thinning. Inferior GDI placement is generally preferred in eyes with silicone oil or that are likely to require retinal detachment repair with silicone oil in the future. Silicone oil is buoyant in aqueous, and an inferior tube minimizes the risk of oil migration through the tube lumen into the subconjunctival space where it can cause inflammation.<sup>23–25</sup>

**Fig. 10.31.1** A polyglactin corneal traction suture is placed to allow intraoperative movement of the globe and facilitate surgical exposure.

**Fig. 10.31.2** A fornix-based conjunctival flap is created.

### Conjunctival Flap and Dissection

A perilimbal 6-0 or 7-0 polyglactin corneal or scleral traction suture facilitates globe movement to optimize visualization during surgery ([Fig. 10.31.1](#)). Blunt scissors and nontoothed forceps are used to create a limbus- or fornix-based flap in the selected quadrant ([Fig. 10.31.2](#)). Hemostasis of the scleral bed is achieved with judicious use of wet-field cautery. Dissection between conjunctiva/Tenon's capsule and sclera is carried posteriorly to create a pocket between the superior and lateral rectus muscles for superotemporal quadrant endplate placement and between the inferior and medial rectus muscles for inferonasal quadrant endplate placement.

### Endplate Attachment

Posterior dissection is followed by identification and isolation of the adjacent rectus muscles. One muscle hook is used to isolate the first rectus muscle, and a second muscle hook is placed immediately behind the first and then slid further posteriorly to reveal a clean scleral pocket beneath the muscle ([Fig. 10.31.3](#)). Care must be taken to hook the entire muscle without splitting it. The endplate is then placed into position 8–10 mm posterior to the limbus between the two adjacent rectus muscles. Each wing of the Baerveldt 250 mm<sup>2</sup> or 350 mm<sup>2</sup> endplate is designed to be tucked beneath adjacent rectus muscle bellies ([Fig. 10.31.4](#)). The Ahmed and single-plate Molteno implants are narrower and may be centered between adjacent rectus muscles. Double-plate Molteno implants occupy two quadrants, and the bridging silicone tube between the two endplates can be tucked under or draped over the superior rectus muscle. The endplate is then

**Fig. 10.31.3** The rectus muscle is isolated and a pocket created for insertion of the endplate.

**Fig. 10.31.4** The endplate is inserted beneath the rectus muscle.

**Fig. 10.31.5** The endplate is secured to sclera 8–10 mm posterior to the limbus using nylon suture on a spatulated needle.

secured to sclera with interrupted nonabsorbable sutures (typically, 8-0 or 9-0 nylon on a spatulated needle), which are passed through each of two eyelets on the anterior edge of the plate (Fig. 10.31.5). The suture knots are buried within the eyelets to prevent future erosion through overlying conjunctiva.

**Fig. 10.31.6** A 7-0 polyglactin ligature is placed near the tube-plate junction to provide flow restriction of the nonvalved tube.

## Implant Preparation

Implants are prepared differently, depending on whether they are valved or nonvalved. The Ahmed implant contains a valve mechanism that requires priming prior to its insertion. Balanced salt solution is injected via a 30-gauge cannula into the tube tip to break the surface tension between the valve leaflets, and patency is confirmed when flow is observed within the device's trapezoidal chamber. This step is generally performed before attachment of the endplate. The endplate should be handled delicately to avoid damaging the valve mechanism.

Nonvalved implants require ligation to provide temporary restriction to flow while capsular fibrosis occurs around the endplate. The tube may be ligated with absorbable (polyglactin) suture (Fig. 10.31.6), which will spontaneously lyse approximately 4–6 weeks after surgery, or nonabsorbable (polypropylene) suture. Polypropylene suture ligation is especially useful in patients at high risk for hypotony; in these patients, laser suture lysis to open the tube in a controlled setting is preferable. If laser suture lysis is planned, the ligature should be placed roughly 5 mm anterior to the tube-plate junction to facilitate later visualization at the slit lamp. After ligation, balanced salt solution is injected by using a 30-gauge cannula to confirm proper tube occlusion. Flow restriction can also be accomplished by using an intraluminal stent or ripcord (4-0 or 5-0 polypropylene or nylon suture) instead of, or in addition to, an external ligature. The end of the stent suture is positioned subconjunctivally in a separate quadrant from the endplate, allowing later removal at the slit lamp once an adequate capsule has formed. Alternatively, a 9-0 polypropylene suture can be used to ligate the distal (intracameral) portion of the tube, and argon laser can be used to later melt the ligature.

Patients who receive a nonvalved implant and have higher preoperative IOP may require interventions to allow aqueous egress and provide IOP reduction in the immediate postoperative period while awaiting tube opening. Venting slits, or fenestrations, may be placed anterior to the ligature using a suture needle or blade (Fig. 10.31.7). The number of fenestrations can be titrated on the basis of the preoperative IOP. Fenestrations have been shown to effectively reduce IOP immediately after GDI surgery but may be accompanied by a greater rate of early hypotony and hypotony-related complications, most of which are transient.<sup>26</sup> Another option is to create a fenestration using the needle of a 9-0 or 10-0 monofilament polyglactin suture and to leave a short segment of the same suture in place to serve as a wick.

## Tube Insertion

Prior to creation of a sclerostomy, a clear corneal paracentesis may be created using a side port blade to allow access to the anterior chamber, if needed. The globe is returned to primary position, and the site of intended tube entry is determined. The tube is then draped across the corneal surface and trimmed with sharp scissors to the desired length, such that 2–3 mm will be visible within the anterior chamber (Fig. 10.31.8). A slightly longer intraocular tube length may be helpful for sulcus and pars plana tubes so that the tube tip can be more easily visualized at the slit

**Fig. 10.31.7** A fenestration is placed anterior to the ligature using a suture needle.

**Fig. 10.31.8** The tube is trimmed with an anterior bevel in preparation for anterior chamber insertion.

**Fig. 10.31.9** A scleral fistula is created by using a 23-gauge needle.

lamp postoperatively. Tubes are trimmed with an anterior bevel for anterior chamber and pars plana entry, and with a posterior bevel for sulcus entry, to avoid iris incarceration.

A 23-gauge needle is bent to a right angle or a slightly obtuse angle by using the jaws of a heavy needle holder, and a sclerostomy is made into the anterior chamber (or sulcus, or pars plana) (Fig. 10.31.9). A short scleral

**Fig. 10.31.10** The tube tip is inserted through the scleral fistula into the anterior chamber and noted to be in good position without proximity to the corneal endothelium or iris.

**Fig. 10.31.11** An interrupted polyglactin suture is placed through episclera to secure the tube just posterior to its site of entry.

tunnel may be created with the 23-gauge needle prior to entry into the eye to help protect the tube from future erosion. The scleral fistula for anterior chamber placement should result in tube placement just above and parallel to the iris plane to avoid proximity to the corneal endothelium (which can cause endothelial dysfunction) or iris contact (which can incite inflammation, or bleeding if rubeosis is present). Nontoothed forceps or a tube inserter (Model TI; New World Medical, Inc., Rancho Cucamonga, CA) is then used to advance the tube tip into the eye through the needle track (Fig. 10.31.10). An 8-0 or 9-0 nylon or 7-0 or 8-0 polyglactin suture in interrupted or figure-of-eight fashion can be used to secure the tube to sclera posterior to its entry site (Fig. 10.31.11). This stabilizing suture should not be tightened excessively because this may impede aqueous flow.

Many surgeons leave cohesive viscoelastic in the anterior chamber when placing a valved implant to minimize the risk of postoperative hypotony. Cohesive viscoelastic is also helpful to tamponade intraoperative bleeding in neovascular eyes.

### Patch Graft Placement

The site of tube entry is covered with a patch graft to minimize the risk of conjunctival erosion and subsequent tube exposure. Several different materials exist for use as a patch graft, including the cornea, sclera, pericardium, dura, and fascia lata. The patch is secured to sclera in at least two points with polyglactin suture, with care taken to completely cover the site of tube entry (Fig. 10.31.12). A longer scleral tunnel may obviate the need for a patch graft and is useful in cases where patch graft material is unavailable.

**Fig. 10.31.12** A corneal patch graft is used to cover the site of tube entry and secured to episclera with polyglactin suture.

**Fig. 10.31.13** The conjunctiva is reapproximated to the limbus and closed using polyglactin suture.

## Conjunctival Closure

Reapproximation of the conjunctiva to the limbus is achieved by using nontoothed forceps. Rotating the eye toward the operated quadrant and loosening the eyelid speculum slightly can facilitate a difficult closure. The conjunctiva is closed using 7-0 or 8-0 polyglactin suture, either in running or interrupted fashion (Fig. 10.31.13). Additional mattress sutures at the limbus help prevent conjunctival retraction. Subconjunctival antibiotics and corticosteroids are administered at the conclusion of the case.

## POSTOPERATIVE MANAGEMENT

Patients are examined on the first postoperative day, and the subsequent frequency of follow-up is determined based on IOP and the general condition of the operated eye. Topical antibiotics and corticosteroids are initiated. Antibiotics can be discontinued at the first postoperative week visit, but corticosteroids are continued for 2–3 months postoperatively. Glaucoma medications may be resumed on the first postoperative day after insertion of a nonvalved GDI unless fenestrations or a wick were placed. Tube opening after nonvalved GDI surgery with an absorbable ligature occurs spontaneously between postoperative weeks 4 and 6 and may be accompanied by a significant and sometimes fibrinous anterior chamber reaction requiring an increase in topical corticosteroid frequency. Because of the risk of hypotony and shallowing of the anterior chamber, patients should be monitored closely during the time the tube is expected to open. Alternatively, laser suture lysis may be performed after adequate encapsulation around the endplate has occurred, which usually requires approximately 4 weeks. Cohesive viscoelastic may be injected intracamerally after laser suture lysis if the IOP is very low or in patients at high risk for hypotony

**TABLE 10.31.2** Potential Complications Associated With Glaucoma Drainage Implants

### Intraoperative Complications

Conjunctival buttonholes or tears  
Hyphema  
Scleral perforation  
Tube truncation

### Postoperative Complications

Anterior chamber shallowing  
Aqueous misdirection  
Bleb encapsulation  
Choroidal effusion  
Corneal decompensation  
Endophthalmitis  
Hypotony maculopathy  
Retinal detachment  
Strabismus and diplopia  
Suprachoroidal hemorrhage  
Tube occlusion  
Tube or endplate exposure  
Tube or endplate migration  
Wound leak

and hypotony-related complications. Argon laser suture lysis settings vary by surgeon preference but usually include a spot size of 50 microns, duration of 0.02–0.05 seconds, and power of 250–800 mW. A Hoskins lens aids in visualization of the ligature.

## COMPLICATIONS

Various complications, some of which are unique to GDI surgery, may arise intraoperatively or postoperatively. These are summarized in Table 10.31.2.

### Intraoperative

An excessively deep scleral pass during endplate or patch graft placement may result in scleral perforation, occasionally causing immediate hypotony and anterior chamber collapse. The needle should be withdrawn from its track and the anterior chamber filled with viscoelastic. An intraoperative or postoperative retinal consult to perform cryotherapy and examine the peripheral retina for breaks may be warranted.

The tube may be inadvertently severed because of an overly tight ligature or overzealous fenestration. Tube extension using a 22-gauge angiocatheter, Crawford tube, or the commercially available Tube Extender (New World Medical, Inc., Rancho Cucamonga, CA) may be needed. If truncation occurs close to the tube–plate junction, then the device may require replacement.

Significant adhesions from prior surgery may impede creation of the initial conjunctival flap. A super sharp blade may help achieve a clean dissection through scar tissue at the limbus. A larger peritomy and relaxing incisions at either extent of the peritomy may mitigate tearing, particularly when the conjunctiva is thin and/or friable.

### Postoperative

Hypotony and its sequelae may occur in the immediate postoperative period because of decreased aqueous production or overfiltration. Aggressive fenestration or excessive flow resulting from wick placement within a nonvalved tube can result in very low pressures. Most cases of hypotony can be managed successfully with conservative therapy (i.e., cycloplegia and topical corticosteroids) and frequent observation if the anterior chamber remains formed. Anterior chamber reformation with viscoelastic may be required in cases where hypotony is accompanied by significant anterior chamber shallowing with lens–endothelial touch and/or large choroidal effusions. Significant choroidal effusions or choroidal hemorrhage may require surgical drainage. Inadequate ligation of a nonvalved device or a valve that is suspected to be malfunctioning may require reoperation.

Hypotony may occur later in the postoperative course, especially when the ligature of a nonvalved tube is released either spontaneously or with laser suture lysis. Frequent follow-up during the time of expected spontaneous tube opening or after ligature release by laser is recommended so that hypotony and its sequelae can be recognized and treated promptly. Cohesive viscoelastic may be placed intracamerally after the tube opens to reform a shallow chamber or in patients at high risk of hypotony-related problems.

Drainage implants are subject to a number of unique complications related to their design. The tube tip may become occluded by fibrin, blood, iris, or vitreous. Obstruction of the tube lumen may be visible during slit-lamp examination, and B-mode echography is helpful to confirm reduced or absent flow around the endplate. Increasing the frequency of topical corticosteroids may melt a fibrinous or hemorrhagic net blocking the tube lumen. Intracameral injection of tissue plasminogen activator (0.1 mL of 5–20 µg/0.1 mL) may be needed in select cases, and carries a risk of hypotony and/or hyphema.<sup>27,28</sup> Iris–tube occlusion may respond to pupillary constriction with pilocarpine and/or application of argon laser to contract iris tissue near or occluding the tube lumen,<sup>29</sup> but surgical revision may be required in refractory cases. Vitreous occlusion of the tube lumen may occur after insertion of a tube into the pars plana after incomplete vitrectomy or delayed hyaloid separation and with anterior chamber or sulcus tubes in the presence of a disrupted posterior capsule or zonular dehiscence. Neodymium:yttrium–aluminum–garnet laser vitreolysis is variably successful, and many patients require repeat pars plana vitrectomy with manual extraction of the vitreous plug from within the tube lumen to completely reverse the occlusion. Obstruction of flow resulting from kinking of pars plana tubes at their entry sites has also been described and may require tube repositioning.<sup>30</sup> Use of an oblique angle, rather than a perpendicular angle, when creating a scleral fistula for pars plana tube insertion helps avoid this complication. Alternatively, the Baerveldt model with a 90° Hoffman elbow designed for pars plana insertion (BG102-350; Abbott Medical Optics, Inc., Santa Ana, CA) may be used.

Endplate migration occurs rarely and can be prevented with proper fixation to the equatorial sclera. Baerveldt glaucoma implants are less likely to migrate because their wings are tucked beneath the adjacent rectus muscles. Tube retraction and anteriorization of the tube tip are more common in children because of reduced scleral rigidity and growth of the eye and may necessitate tube extension and/or repositioning.

Erosion of the conjunctiva overlying a tube may result from eyelid rubbing, repetitive eye movements, poor ocular surface lubrication, immunological factors, and/or vector forces at the site of tube entry. Directing tube entry close to the 12 o'clock position for superotemporal implants and the 6 o'clock position for inferonasal implants minimizes this risk, as the site of tube entry is always covered by the eyelid in these locations.<sup>31</sup> Tube

exposure is a major risk factor for endophthalmitis,<sup>32,33</sup> and its recognition should prompt immediate initiation of topical antibiotics and timely surgical intervention. Replacement of the patch graft may suffice in select cases of limited tube exposure, but tube repositioning through a new scleral fistula is often needed. Glaucoma drainage implant removal may be required with large erosions over the tube, or if erosion has occurred over the endplate.

Bleb encapsulation, or hypertensive phase, occurs more commonly with valved than nonvalved devices.<sup>34,35</sup> Development of a thick-walled bleb contributes to decreased permeability of aqueous through the conjunctiva, resulting in at times severe IOP elevation. Exposure to inflammatory mediators within the aqueous may contribute to increased fibrosis.<sup>34</sup> Aqueous suppression usually lowers the IOP sufficiently for bleb remodeling to occur, but resolution may require weeks to months. Bleb needling or additional glaucoma surgery may be required in refractory cases.<sup>36</sup>

Corneal decompensation may occur as a result of improper tube positioning within the anterior chamber, prolonged hypotony resulting in contact between the native lens or intraocular lens implant and endothelium, or immunological factors. Meticulous intraoperative positioning of the tube far from the corneal endothelium usually avoids this complication, but some patients with pseudo-phakia or aphakia may require tube repositioning to the sulcus or pars plana and corneal transplantation surgery.

Strabismus and diplopia may occur after GDI placement as a result of scarring, mass effect of the endplate or a large resulting bleb, and fat fibrosis.<sup>16,37</sup> Sufficiently posterior endplate placement to avoid crowding of the rectus muscle insertions and avoidance of the superonasal quadrant help avoid this complication. Most cases of diplopia are transient, but some patients may require aqueous suppression to reduce an exuberant bleb, prisms, strabismus surgery, or, rarely, implant removal.

EVIDENCE FROM RANDOMIZED CLINICAL TRIALS

A number of randomized clinical trials have compared the outcomes of drainage implantation and trabeculectomy as well as different drainage implants. Their findings are summarized in Table 10.31.3.

TABLE 10.31.3 Randomized Clinical Trials Evaluating Glaucoma Drainage Implants			
Author (year)	N	Study Groups	Key Results
Drainage Implants Versus Trabeculectomy			
Wilson et al. (2003) <sup>38</sup>	123	Ahmed glaucoma valve (S2) Trabeculectomy with mitomycin C	Lower IOP in trabeculectomy group during postoperative year 1 Similar IOP in both groups after postoperative year 1 No difference in visual outcomes, number of medications, success rates, or complication rates at final follow-up
Gedde et al. (2012) <sup>39</sup>	212	Baerveldt glaucoma implant (350 mm <sup>2</sup> ) Trabeculectomy with mitomycin C	Higher rates of failure and reoperation for glaucoma in trabeculectomy group Similar IOP and number of medications in both groups More frequent early complications in trabeculectomy group Similar rates of late and serious complications in both groups Similar visual outcomes in both groups
Valved Versus Nonvalved Drainage Implants			
Nassiri et al. (2010) <sup>41</sup>	92	Ahmed glaucoma valve (FP7) Molteno implant (single-plate)	Similar success rates in both groups Similar IOP, number of medications, and visual acuity in both groups at 2 years No devastating complications in either group
Budenz et al. (2015) <sup>42</sup>	276	Ahmed glaucoma valve (FP7) Baerveldt glaucoma implant (350 mm <sup>2</sup> )	Similar failure rates in both groups at 5 years Lower IOP in Baerveldt group after month 1 Fewer medications required by Baerveldt group at 5 years Higher rate of serious complications in Baerveldt group at 5 years Similar visual outcomes in both groups
Christakis et al. (2016) <sup>35,44</sup>	238	Ahmed glaucoma valve (FP7) Baerveldt glaucoma implant (350 mm <sup>2</sup> )	Lower failure rates in Baerveldt group at 5 years Lower IOP in Baerveldt group after month 1 Less medications required by Baerveldt group at 5 years Higher rate of hypotony-related vision-threatening complications in Baerveldt group at 3 years Similar visual outcomes in both groups
Drainage Implants of Different Endplate Size			
Heuer et al. (1992) <sup>45</sup>	132	Molteno implant (single-plate) Molteno implant (double-plate)	Higher success rates in double-plate group More frequent choroidal hemorrhage in double-plate group Similar visual outcomes in both groups
Lloyd et al. (1994) <sup>46</sup>	73	Baerveldt glaucoma implant (350 mm <sup>2</sup> ) Baerveldt glaucoma implant (500 mm <sup>2</sup> )	Similar success rates in both groups at 18 months
Britt et al. (1999) <sup>47,a</sup>	107	Baerveldt glaucoma implant (350 mm <sup>2</sup> ) Baerveldt glaucoma implant (500 mm <sup>2</sup> )	Higher success in 350 mm <sup>2</sup> group at 5 years Similar IOP and number of medications in both groups at 5 years Similar rates of vision loss and complications in both groups
<sup>a</sup> Follow-up study to Lloyd et al. (1994) <sup>46</sup> enrolling an additional 34 patients and reporting outcomes for a total of 107 patients through 5 years. IOP, Intraocular pressure; N, number of enrolled patients.			

## Drainage Implants Versus Trabeculectomy

Surgical outcomes of drainage implantation and trabeculectomy were directly compared in a prospective trial by Wilson et al.,<sup>38</sup> who randomized 123 patients with glaucoma and without prior intraocular surgery to undergo trabeculectomy with mitomycin C (0.3–0.4 mg/mL for 3–4 minutes) or placement of an Ahmed glaucoma valve (S2). Although lower mean IOP was achieved by the trabeculectomy group during postoperative year 1, similar IOPs were observed in the trabeculectomy and Ahmed groups thereafter. Success rates, adjunctive medications, visual outcomes, and complication rates were comparable between the two groups at the final (41- to 52-month) follow-up interval.

The Tube Versus Trabeculectomy (TVT) Study<sup>39</sup> randomized 212 patients with previous cataract extraction and intraocular lens implantation and/or failed filtering surgery to undergo Baerveldt glaucoma implantation (350 mm<sup>2</sup>) surgery or trabeculectomy with mitomycin C (0.4 mg/mL for 4 minutes). At postoperative year 5, IOP and number of medications were similar between the two groups. Failure (i.e., IOP >21 mm Hg or <20% reduction, IOP ≤5 mm Hg, additional glaucoma surgery, or loss of light perception) occurred more frequently in the trabeculectomy group (46.9%) than in the tube group (29.8%) over 5 years of follow-up ( $P = 0.002$ ). The trabeculectomy group also had a higher rate of reoperation for glaucoma compared with the tube group (29% trabeculectomy group versus 9% tube group,  $P = 0.025$ ). Although early postoperative complications (i.e., those occurring within postoperative month 1) were more common in the trabeculectomy group (37% trabeculectomy group versus 21% tube group,  $P = 0.012$ ), rates of late postoperative complications (36% trabeculectomy group versus 34% tube group,  $P = 0.81$ ) and serious complications needing reoperation and/or producing loss of ≥2 Snellen lines (18% trabeculectomy group versus 22% tube group,  $P = 0.29$ ) were similar between the two groups.<sup>40</sup> Similar visual outcomes were reported for both groups at 5 years. Results from the TVT Study support an expanded role for GDIs beyond the refractory glaucomas, to which they have traditionally been relegated.

## Valved Versus Nonvalved Drainage Implants

Outcomes of implantation of the Ahmed glaucoma valve (FP7) and single-plate Molteno drainage device were compared in a prospective, randomized study of 92 patients with refractory glaucoma (i.e., IOP >21 mm Hg using maximal medical therapy and/or failed non-GDI glaucoma surgery).<sup>41</sup> Rates of success (i.e., IOP <21 mm Hg and >6 mm Hg without phthisis bulbi, loss of light perception, GDI removal, additional glaucoma surgery, or devastating complications) over 2 years of follow-up were similar between groups (82% Ahmed group versus 84% Molteno group,  $P = 0.65$ ). Lower IOP was achieved in the Ahmed group at day 1 and week 1 ( $P < 0.001$ ) as would be expected after implanting a valved device, but the Molteno group achieved lower IOP thereafter ( $P < 0.01$ ) through the 2-year study endpoint. The number of glaucoma medications and visual acuity were similar in both groups at all time points. No devastating complications occurred in either group.

The Ahmed Baerveldt Comparison (ABC) Study<sup>42,43</sup> and Ahmed Versus Baerveldt (AVB) Study<sup>35,44</sup> both compared the outcomes of placement of the Ahmed glaucoma valve (FP7) and the Baerveldt glaucoma implant (350 mm<sup>2</sup>) in patients with refractory glaucoma. The ABC Study and AVB Study randomized a total of 276 and 238 patients, respectively. Failure was defined somewhat differently in the two trials (i.e., IOP >21 mm Hg or <20% reduction, IOP ≤5 mm Hg, reoperation for glaucoma, implant removal, or loss of light perception in the ABC Study and IOP >18 mm Hg or <20% reduction, IOP <5 mm Hg, reoperation for glaucoma, vision-threatening complication, or loss of light perception in the AVB Study), although they shared a similar study design. Although mean IOP was significantly lower in the Ahmed group during the first few postoperative weeks in both studies, the Baerveldt group demonstrated greater sustained reductions in IOP after postoperative month 1. The Baerveldt group also required fewer medications at 5 years than the Ahmed group in both studies. Failure rates were lower in the Baerveldt group at 5 years in the AVB Study (40% Baerveldt group versus 53% Ahmed group,  $P = 0.04$ ), but similar between groups at 5 years in the ABC Study (39.4% Baerveldt group versus 44.7% Ahmed group,  $P = 0.65$ ). Serious complications requiring reoperation or associated with loss of 2 or more Snellen lines were more common in the Baerveldt group over 5 years in the ABC Study (24.7% Baerveldt group versus 15.9% Ahmed group,  $P = 0.034$ ).<sup>43</sup> The Baerveldt group had a higher rate of hypotony-related vision-threatening complications at 3 years in the

AVB Study (6% Baerveldt group versus 0% Ahmed group,  $P = 0.005$ ).<sup>44</sup> Visual outcomes were comparable in both groups in both studies.

## Drainage Implants of Different Endplate Sizes

A randomized trial comparing outcomes of single-plate implants versus double-plate Molteno implants in 132 aphakic and pseudo-phakic eyes with nonneovascular glaucoma found a higher rate of success (i.e., IOP ≥6 mm Hg and ≤21 mm Hg without additional glaucoma surgery or devastating complication) in the double-plate group at 2 years (71% double-plate group versus 46% single-plate group,  $P = 0.0035$ ).<sup>45</sup> Visual outcomes were similar between the two groups. Choroidal hemorrhage was significantly more common in the double-plate group than in the single-plate group (8% double-plate group versus 0% single-plate group,  $P = 0.043$ ). Other complications, including serous choroidal effusions, flat anterior chamber, and corneal decompensation, also occurred more frequently in the double-plate group, but these differences were found to be not statistically significant.

Lloyd et al.<sup>46</sup> randomized 73 patients with nonneovascular glaucoma and aphakia, pseudo-phakia, or failed filtering surgery to undergo placement of a 350 mm<sup>2</sup> or 500 mm<sup>2</sup> Baerveldt implant. Success rates (i.e., IOP ≥6 mm Hg and ≤21 mm Hg without additional glaucoma surgery, devastating complications, or loss of light perception) were similar between the two groups at 18 months (93% in 350 mm<sup>2</sup> versus 88% in 500 mm<sup>2</sup>,  $P = 0.93$ ). Britt et al.<sup>47</sup> recruited 34 additional patients and reported longer-term results for a total of 107 patients. Over 5 years of follow-up, a higher success rate was observed among patients receiving a 350 mm<sup>2</sup> implant compared with those receiving a 500 mm<sup>2</sup> implant (79% in 350 mm<sup>2</sup> group versus 66% in 500 mm<sup>2</sup> group,  $P = 0.05$ ), suggesting that additional surface area beyond a certain threshold does not contribute to greater surgical success. IOP and number of medications were similar between the two groups at 5 years. Rates of vision loss and complications were also comparable between the 350 mm<sup>2</sup> group and the 500 mm<sup>2</sup> group.

## CONCLUSIONS

Drainage implants are routinely used in the surgical management of glaucoma, and their role has expanded in recent years to include use in eyes at lower risk for trabeculectomy failure. Randomized clinical trials have provided invaluable information supporting the relative efficacy of drainage implants in comparison with trabeculectomy and comparisons of different types of drainage implants. Glaucoma drainage implant surgery may be associated with certain unique complications, some of which can be avoided with careful preoperative planning and diligent intraoperative technique.

[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** Untoward events occurring with glaucoma surgery intraoperatively or postoperatively that can limit the success of the surgery.

## Key Features

- Can occur in the intraoperative, early postoperative, or late postoperative period.
- May or may not be technique dependent.
- May cause pain, decreased vision, double vision, irritation, or loss of vision.

## Associated Features

- Conjunctival buttonhole.
- Intraocular hemorrhage.
- Hypotony.
- Shallow anterior chamber.
- Infection.
- Cataract.
- Diplopia.

## INTRODUCTION

The primary goal of glaucoma surgery is to preserve the vision and ocular health of the patient by preventing disease progression. Improving the patient's function is crucial. This cannot be achieved by procedures that result in decreased visual acuity or increased discomfort. Therefore, steps should be taken to avoid lowering intraocular pressure (IOP) too much, thereby causing disability as a result of pain, photophobia, or double vision. The increased use of antimetabolite therapy during surgery has led to more postoperative complications. Techniques should be modified to avoid complications, and with proper selection, patients should be matched with appropriate surgical approaches.

## TRABECULECTOMY

Complications associated with trabeculectomy surgery can occur intraoperatively, early postoperatively, and late postoperatively.

### Intraoperative Complications

#### Conjunctival Buttonhole

Meticulous technique is the best way to avoid complications associated with glaucoma surgery. This axiom is certainly appropriate in the management of buttonholes of the conjunctiva. Toothed forceps should not be used when handling the conjunctiva. In addition, the conjunctiva should be touched only with the initial incision—whether the fornix or limbal approach is used. Tenon's layer should be manipulated to direct the conjunctival dissection. If a buttonhole does occur, proper management requires immediate attention, as further manipulation will likely enlarge the buttonhole. Complete closure of the buttonhole is necessary to achieve successful results. If complete closure cannot be ensured, then rotation of

the site of the trabeculectomy flap to a different area should be considered. Conjunctival buttonholes come in different locations, sizes, and shapes. They can occur near the limbus, in the midportion of the bleb, or posteriorly. An 8-0 or 9-0 polyglactin suture on a vascular needle in a horizontal mattress fashion can be used to close a small hole, or in a running fashion with single-layer or double-layer closure for larger holes. A “clothesline” suturing technique has been described for repair of buttonholes.<sup>1</sup>

#### Trabeculectomy Scleral Flap Tear/Disinsertion

The surgeon should create a scleral flap that is about two thirds depth of the total scleral thickness. Occasionally, a “ratty” or thin sclera leads to a flap that tears or disinserts. If the tear is small, the flap can be repaired with a 10-0 nylon suture. If the flap disinserts completely, an attempt can be made to reposition the flap by rotating the thicker part of the flap over the sclerectomy. There are reports of successful repositioning of a totally disinserted flap using two 10-0 nylon sutures through the flap base and out the peripheral cornea.<sup>2</sup> Often, however, the quality of the sclera is so poor that placement of sutures through the original flap is not possible because of a “cheesewire” effect, and placement of an additional cover over the flap becomes necessary. Choices of cover material include donor sclera,<sup>3</sup> dura, pericardium, or even fascia lata.<sup>4</sup> Cornea tissue and amniotic membrane have also been used for this repair.<sup>5,6</sup> A rectangular piece of the material of choice is prepared and fashioned to be approximately 2 mm larger and wider than the trabeculectomy flap. The cover is sutured into place with at least one 10-0 nylon suture to each corner of the material. Postoperatively, these sutures may be lysed using an argon laser to increase drainage, as desired.

#### Intraoperative Bleeding

Excessive bleeding from the iris vessel/root most commonly occurs at the time of iridectomy. Bleeding occurs from cut radial vessels or from a traumatized greater arterial circle within the ciliary body. Such bleeding can be observed, as most iris root/ciliary body bleeding will stop spontaneously within minutes. Applying pressure to the area with a cellulose sponge may speed clot formation. Excess cautery should be avoided because it may lead to vitreous presentation. Cautery should be applied liberally to the scleral flap bed prior to making the scleral flap incision, and the scleral flap should not be sutured until all of the bleeding has stopped. Premature suturing often leads to postoperative blockage of the internal ostium by the clotted blood.

A suprachoroidal hemorrhage (SCH) can occur during surgery, the hallmark being shallowing of the anterior chamber in the presence of an enlarging dark posterior segment mass visible through the pupil. If an intraoperative choroidal hemorrhage is suspected, the wound should be closed immediately. The anterior chamber should be reformed with air or a viscoelastic agent. Once the eye has been closed, intravenous acetazolamide and mannitol can be used to lower IOP. Drainage of the hemorrhage may be necessary later. Immediate recognition of SCH is paramount, because an expulsive choroidal hemorrhage is disastrous. The risk of SCH is reportedly higher in patients with high myopia, aphakia, or pseudo-phakia, in vitrectomized patients, in patients with bleeding disorders, and in the presence of elevated blood pressure. The results of the Fluorouracil Filtering Study<sup>7</sup> showed that only high preoperative IOP was associated with a statistically significantly increased risk of SCH. None of the 63 patients with a preoperative IOP less than 30 mm Hg developed SCH.

Preoperatively, it is important to check IOP when the patient is in the holding area. Intravenous mannitol (1–2 g/kg) is recommended if the IOP is greater than 30 mm Hg. Mannitol has an onset of action of less than an hour, so if it is given prior to the surgery, the IOP should be significantly lower before an intraocular incision is made. Furthermore, blood pressure should be monitored and treated if it is elevated.

Intraoperatively, the risk of SCH may be reduced by decompressing the eye slowly and carefully with the initial paracentesis. In addition, it is important to suture the scleral flap snugly and to achieve meticulous conjunctival wound closure. Leaving the eye partially filled with viscoelastic can be considered to minimize the likelihood of anterior chamber shallowing in the early postoperative period.

## Early Postoperative Complications

### Shallow Anterior Chamber

Shallow anterior chamber in the early postoperative period can be associated with low or high IOP. It is important to have a system of measuring the central anterior chamber depth to determine if anterior chamber shallowing is progressive. It is not adequate simply to note “shallow anterior chamber” in the record because a more objective measure is necessary to determine response to therapy. One system involves notating the central anterior chamber depth based on the modified van Herick technique (Fig. 10.32.1). This technique compares the central anterior chamber depth with the thickness of the central cornea.

**Fig. 10.32.1 Modified van Herick Technique to Assess Peripheral Anterior Chamber Depth.** The same technique can be applied to the central anterior chamber. (Modified with permission from Shields MB. Textbook of Glaucoma. 3rd ed. Baltimore, MD: Williams & Wilkins, 1992.)

Shallow chamber associated with low IOP suggests either overfiltration and/or a bleb leak. Overfiltration results from inadequate scleral flap closure resulting in a high bleb. If the bleb is high and no corneal–lens touch or appositional choroidal effusion occurs, observation with a cycloplegic agent is appropriate. If anterior chamber shallowing is progressive, injection of viscoelastic material into the anterior chamber may lead to early “scarring” of the bleb and decreased aqueous outflow with subsequent deepening of the anterior chamber.<sup>8</sup> Viscoelastic material with greater viscosity is particularly helpful in such cases. It is useful to use the pre-existing paracentesis site created during surgery to facilitate postoperative access to the anterior chamber. Trying to create a new access port in soft eyes, especially phakic ones, can be challenging. Alternatively, some surgeons use a “torpedo” patch that is created by placing a fusiform-shaped cotton ball over the lid in the area of the trabeculectomy flap.<sup>9</sup> This cotton ball is held in place with gauze pads to act as a tamponade (Fig. 10.32.2). If this type of pressure dressing is used, the patient should be kept awake, with the fellow eye open and looking straight ahead, because Bell’s phenomenon of sleep may place the tamponade over the center of the cornea. If overfiltration continues with the development of choroidal effusions that touch, or of lens–corneal touch, a return to the operating room for further flap closure, anterior chamber reformation, and effusion drainage may be indicated.

Initial “overfiltration” with a bleb leak may frequently be the result of a buttonhole missed at the time of surgery. A buttonhole is far more difficult to manage postoperatively. On examination, these patients generally are found to have a low or flat bleb. It is important to use 2% fluorescein to stain the bleb because more dilute fluorescein agents may not discern a slow leak. Patching techniques or the placement of an oversized bandage contact lens may be used initially. Other options include autologous fibrin tissue glue,<sup>10</sup> autologous blood injection (Fig. 10.32.3),<sup>11–14</sup> and cyanoacrylate glue with contact lens application.<sup>15</sup> A large, early-postoperative bleb leak may require a return to the operating room to develop a new conjunctival flap from tissue posterior to the defect.<sup>16</sup>

One other cause of a shallow anterior chamber associated with low IOP in the early postoperative period is ciliary body shutdown secondary to intense postoperative inflammation. Such eyes present with flat blebs, no bleb leaks, shallow anterior chambers, low IOP, and occasionally inflammatory choroidal effusions. Postoperative 5-fluorouracil injections should be considered to help prevent subconjunctival adhesions in the period before aqueous flow resumes. Occasionally, mitomycin will also lead to ciliary body shutdown early postoperatively because of cytotoxic effects on the ciliary epithelium.<sup>17</sup>

Shallow anterior chamber associated with high IOP in the early postoperative period can result from an incomplete iridectomy with pupillary block, delayed SCH, or aqueous misdirection (malignant) (see Chapter 10.19) glaucoma. If the presence of a full-thickness iridectomy can be confirmed postoperatively, pupillary block can be ruled out. However, if doubt exists with regard to the patency of the surgical iridectomy, a laser iridectomy or surgical iridectomy should be performed as soon as possible (Fig. 10.32.4). Once a pupillary block is excluded, the presence of SCH should be determined. Patients with SCH generally present during the first few postoperative days with severe pain, occasional nausea, and a marked reduction in vision. IOP is usually, but not always, elevated; the anterior chamber is shallow or flat; and large choroidal detachments, often with central apposition, are present. If ophthalmoscopy is not helpful, B-scan ultrasonography will be necessary (Fig. 10.32.5). Management of a patient with a delayed SCH involves observation and corticosteroid and cycloplegic therapy initially. If there is no clinical improvement, evacuation of the SCH in the operating room should be considered. Vitrectomy with the instillation of an intraocular expandable gas can be useful to facilitate return of the retina and choroid to their anatomical positions. There is some debate among the vitreoretinal community, however, regarding the optimal time to intervene. Some recommend waiting 7–10 days following the hemorrhage to allow for the clot to liquefy, but others favor intervening earlier to allow for quicker visual recovery.<sup>18</sup>

Another cause of shallow anterior chamber with high IOP is aqueous misdirection. Forward displacement of the vitreous into apposition with the iris and ciliary body, possibly associated with thickening of the anterior hyaloid, has traditionally been proposed as the mechanism.<sup>19</sup> Posterior pooling of aqueous humor, either within or behind the vitreous, causes forward movement of the lens–iris or hyaloid–iris diaphragm, resulting in a flat anterior chamber with elevated IOP. Medical treatment of aqueous misdirection with cycloplegic therapy and aqueous suppressants and/or osmotics is successful in about 50% of cases. Other useful medical adjuncts include phenylephrine 2.5% and frequent topical corticosteroids.

**Fig. 10.32.2** Pressure patch technique. (From Shields MB. Textbook of Glaucoma. 3rd ed. Baltimore, MD: Williams & Wilkins, 1992.)

**Fig. 10.32.3** (A) Bleb appearance immediately after autologous blood injection. (B) Suspended heme in viscoelastic-filled anterior chamber after autologous blood injection.

Therapy also may include argon laser treatment of visible ciliary processes, neodymium:yttrium–aluminum–garnet (Nd:YAG) anterior hyaloidectomy, or possible capsulectomy, in aphakic and pseudo-phakic eyes. Surgical therapy is necessary if these medical and laser techniques are ineffective. Pars plana vitrectomy with rupture of the vitreous face often produces definitive results.

### Low Filtration

In the early postoperative period, low filtration is a consideration when the bleb is low and not associated with a bleb leak and the anterior chamber is deep. IOP may be high, normal, or low, depending on the level of aqueous production. It is important to confirm with gonioscopy that the sclerectomy

is not blocked by blood or fibrin. Low filtration is managed by sequential release of scleral flap sutures. The appearance of the bleb, not necessarily IOP, should guide the decision to perform laser suture lysis. If permanent sutures have been placed, the suture may be lysed with the argon laser and a Hoskins (or Ritch) lens.<sup>20</sup> Krypton red (or blue–green argon) 50  $\mu$ m spot size at 300 mW are usually effective settings. To improve the success of suture lysis postoperatively, it is helpful to intraoperatively place the nylon suture that is as long as possible and to note which suture was associated with the best flow at the time of surgery, so as to be selectively efficient in postoperative management. A partial tenonectomy can be useful to improve visualization of the scleral sutures. Alternatively, several releasable suture techniques are available if difficulty with suture visualization

**Fig. 10.32.4** (A) Shallow anterior chamber after glaucoma drainage tube placement. (B) Deeper anterior chamber after surgical peripheral iridectomy.

**Fig. 10.32.5** B-scan ultrasonography picture of a suprachoroidal hemorrhage.

postoperatively is anticipated.<sup>21-23</sup> If the sclerectomy is blocked by fibrin or blood, tissue plasminogen activator may be helpful.<sup>24,25</sup>

### Choroidal Effusion

Although posterior choroidal effusions (Fig. 10.32.6) often occur in conjunction with shallow anterior chamber and low IOP. They may also occur in eyes that have full-depth chambers and low IOP. Management usually consists of cycloplegia, topical corticosteroids, and observation. As long as the effusions do not touch ("kiss"), drainage is usually not required. If touch does occur centrally, many surgeons choose to perform effusion drainage via posterior sclerotomies inferiorly because of the potential danger of retinal adhesion formation and the profound effect on visual function.

**Fig. 10.32.6** Photo of serous choroidal effusion ("kissing" choroidals).

**Fig. 10.32.7** Hypotonous maculopathy.

## Late Postoperative Complications

### Late Hypotony

Antimetabolites have introduced a new entity, late hypotony, to the list of postoperative trabeculectomy complications. Most commonly, the history is of mitomycin use, with loose scleral flap closure leading to IOP in the low single digits. Characteristically, vision is decreased, the eye is soft, and the bleb is large, thin, and avascular. Retinal and/or choroidal folds may be seen in the macula (Fig. 10.32.7), in association with tortuous retinal vessels and a swollen optic nerve head. Available treatments include autologous blood injection,<sup>11,26</sup> compression suture placement,<sup>27</sup> and Nd:YAG bleb treatment.<sup>28</sup> If these measures fail, a return to the operating room to revise the thin bleb and/or resuture the flap is indicated.<sup>14,29</sup> A donor patch graft over the scleral flap may be necessary to limit aqueous egress. Alternatively, if a symptomatic cataract is present, the cataract extraction-associated inflammation frequently slows filtration through bleb "scarring" and may resolve the hypotony.<sup>30</sup>

### Late Bleb Failure

Late bleb failure may result from heavy vascularization and healing around the bleb as well as episcleral fibrosis.<sup>31,32</sup> Digital pressure applied by the patient to the inferior globe through the inferior lid (Fig. 10.32.8) may be useful in such cases because this helps maintain flow through the drain

## DIGITAL PRESSURE FOR EYE WITH FAILING FILTERING BLEB

**Fig. 10.32.8** Digital pressure for eye with failing filtering bleb. (Reproduced with permission from Shields MB. Textbook of Glaucoma. 3rd ed. Baltimore, MD: Williams & Wilkins, 1992.)

**Fig. 10.32.9** Small pupil after maximal dilation resulting from posterior synechiae after trabeculectomy surgery.

and keeps the subconjunctival space expanded. If this is insufficient, needle revision of the bleb may re-establish effective filtration.<sup>33,34</sup>

### Cataract Formation

Cataracts are very common in the older population. The cataracts often get worse because of the effect of glaucoma medications<sup>35</sup> and after trabeculectomy surgery.<sup>36</sup> Cataracts can progress secondary to postsurgical events, such as shallow anterior chamber. Cataract surgery may be complicated in these patients because of small pupils caused by posterior synechiae (Fig. 10.32.9) or pseudo-exfoliation. Various techniques to open the pupil during cataract surgery have been described and are usually associated with good visual recovery.<sup>37-39</sup> One technique of opening the pupil involves the use of the I-Ring (Beaver Visitec, Waltham, MA) (Video 10.32.1). One concern, however, is the long-term success of the filtering bleb after the cataract surgery. Klink et al.<sup>40</sup> showed that IOP increased about by 2 mm Hg at 12 months postoperatively in patients who had phacoemulsification after trabeculectomy.

### Late Bleb Leaks

It is predicted that the incidence of late bleb leaks will increase over time because of the increased use of antimetabolites. Initial management of these leaks involves patching, aqueous suppression, antibiotics, and bandage contact lenses. There are numerous additional options, including glue, autologous blood injection, trichloroacetic acid application, cryotherapy, and Nd:YAG laser remodeling. If these less invasive alternatives are not successful, a return to the operating room is necessary to excise the ischemic bleb from the eye and advance the posterior conjunctival edge to the limbus<sup>14</sup> (Video 10.32.2).

### Blebitis and Endophthalmitis

As many as 1 per 100 patients/year may develop infection of the bleb. The cystic thin blebs seen after antimetabolite application are believed to have a higher risk. Blebitis is differentiated from conjunctivitis by the presence of a chalky white bleb with surrounding conjunctival injection often associated with a bleb leak. If the vitreous is quiet, prompt treatment with hourly topical antibiotics may save the bleb and prevent true endophthalmitis. Topical corticosteroids after 48 hours of treatment are useful to treat the inflammation. The prompt treatment of blebitis is generally effective. However, if endophthalmitis with vitreous involvement is diagnosed, intra-vitreous cultures and antibiotics and possible vitrectomy are required. The prognosis for salvaging such eyes is guarded. Organisms frequently seen in these eyes include *Hemophilus*, streptococci, and staphylococci. Thus, coverage is best initiated with fortified topical cefazolin or vancomycin and tobramycin. Intravitreal antibiotic injections of choice include vancomycin and amikacin. It is very important to instruct patients about early recognition of infection and to seek medical attention promptly if there is any suspicion of infection.

### GLAUCOMA DRAINAGE IMPLANTS

With the introduction of newer designs and the publication of studies, such as the Tube Versus Trabeculectomy (TVT) trial, drainage implants are gaining wider acceptance in the ophthalmology community.<sup>41,42</sup> The TVT trial showed that at 5 years after surgery, in eyes with previous incisional surgery, the IOP-lowering effect of Baerveldt (Abbott Medical Optics, Irvine, CA) drainage implantation is equivalent to that of trabeculectomy surgery. The filtration blebs associated with drainage devices are located more posteriorly compared with those seen with trabeculectomy surgery, which may decrease bleb-related concerns, such as infection and discomfort. Some complications associated with glaucoma drainage tube implantation include diplopia, corneal decompensation, tube exposure (Fig. 10.32.10), and glaucoma drainage plate exposure.

Development of new devices and technologies for glaucoma surgery was spurred by the realization that the standard surgeries performed today for glaucoma have unacceptably high failure and complication rates even when performed as primary surgeries.<sup>43</sup> Minimally invasive glaucoma surgery (MIGS) aims to provide a safer, less invasive means of reducing IOP compared with traditional surgery, with the goal of reducing dependency on topical medications. To date, the current MIGS procedures offer more modest IOP-lowering results compared with traditional glaucoma surgery, but with the benefit of a safer risk profile. Thus, these procedures are indicated in patients with mild-to-moderate glaucoma. MIGS can be defined as any glaucoma procedure avoiding conjunctival dissection and thus approached via an ab interno incision. Although safer than traditional surgery, hyphema is fairly common after these procedures, but it usually resolves spontaneously. Contraindications to performing these procedures include inability to stop anticoagulation medication, bleeding diathesis, closed angle, and inability to identify trabecular meshwork.

# Genes Associated With Human Glaucoma

Janey L. Wiggs

10.33

**Definition:** The genetic component underlying the pathogenesis of many of the heterogeneous diseases referred to as *glaucoma*.

**Key Features**

- Congenital or juvenile onset.
- Familial predisposition.

**Associated Feature**

- Possibility of diagnostic testing to predict glaucoma risk.

INTRODUCTION

For many years, a family history of glaucoma has been recognized as an important disease risk factor. Some forms of glaucoma are inherited as mendelian dominant or recessive traits, including juvenile open-angle glaucoma, congenital glaucoma, developmental glaucomas (Rieger’s syndrome and aniridia), and pigmentary glaucoma. Other types of glaucoma, such as adult primary open-angle glaucoma (POAG), have a heritable susceptibility.<sup>1</sup> At least one gene has been identified for most types of glaucoma (Table 10.33.1).

The identification of genes that contribute to glaucoma and characterization of the normal and abnormal biological function of the protein products of these genes can provide important new information about the pathophysiology of the disease. Current treatment for glaucoma is directed toward the regulation of aqueous humor formation by the ciliary body and increased outflow of aqueous humor through the trabecular meshwork or alternative pathways created by surgical procedures. Current therapy does not actually treat the cause of the disease because the molecular and cellular basis of disease in most cases is unknown. Identifying genes responsible for glaucoma and determining the functions of the normal and abnormal protein products will define the underlying molecular processes contributing to disease. This information could lead to the development of novel treatments, including gene-based therapies. The isolation of genes responsible for glaucoma will also lead to new methods for diagnosis based on the DNA sequence changes that result in defective genes and protein products. Such DNA-based diagnostic tests can identify individuals at risk for the disease before any visual deterioration has occurred.

TABLE 10.33.1 Genes Causing Glaucoma With Mendelian Inheritance (Autosomal Dominant and Autosomal Recessive)

Condition	Gene
Juvenile open-angle glaucoma	MYOC
Congenital glaucoma	CYP1B1
	LTBP2
	TIE2 (TEK)
Developmental glaucoma	FOXC1
	PITX2
	PAX6 (aniridia)
Familial normal-tension glaucoma	OPTN
	TBK1
Nanophthalmos	MFRP

CONGENITAL GLAUCOMA

Congenital glaucoma can be inherited as an autosomal recessive or autosomal dominant trait. Two genes responsible for autosomal recessive disease have been identified: *CYP1B1*, coding for cytochrome *P450**1B1*<sup>2,3</sup> and *LTBP2*, coding for latent transforming growth factor-beta (TGF-β)–binding protein 2.<sup>4</sup> Subsequently, mutations in *CYP1B1* have been identified in patients worldwide, whereas *LTBP2* appears to be more localized to specific populations where consanguineous marriages are common.<sup>5–7</sup> Glaucoma-associated *CYP1B1* mutations disrupt protein functional domains, implying that loss of function (LOF) of the protein results in the phenotype.<sup>8</sup> Variability in the phenotypic expression of mutant forms of *CYP1B1* has led to the suggestion that modifier genes may also influence the severity of the disease resulting from mutations in this gene.<sup>9</sup> One study indicated that patients carrying *MYOC* mutations in addition to *CYP1B1* mutations have more severe disease, suggesting that the proteins of these two genes may interact in the same biochemical pathways.<sup>10</sup> Disease severity has also been shown to be modified by tyrosinase in a *CYP1B1* knockout model; however, tyrosinase does not appear to be a major modifier gene in humans with *CYP1B1* mutations.<sup>11,12</sup>

TIE2 (TEK) LOF mutations can cause congenital glaucoma with autosomal dominant inheritance and variable expressivity.<sup>13</sup> Homozygous *Tie2* knockout mice without functional TEK (tunica interna endothelial cell kinase) have high intraocular pressure and buphthalmos secondary to absence of Schlemm’s canal.<sup>14</sup> Humans with heterozygous loss function *TIE2* mutations have a range of glaucoma phenotypes extending from congenital onset to adult onset. Presumably, the variation in glaucoma onset correlates with the extent that Schlemm’s canal developed.

DEVELOPMENTAL GLAUCOMA

In humans, primarily three genes—*PITX2*, *FOXC1*, *PAX6*—have been associated with abnormal anterior segment development and glaucoma.<sup>15–17</sup> Mutations in *PITX2* located on chromosome 4q25 cause Rieger’s syndrome, which is an autosomal dominant disorder of morphogenesis that results in abnormal development of the anterior segment of the eye. Typical clinical findings may include posterior embryotoxon, iris hypoplasia, iridocorneal adhesions, and corectopia. Approximately 50% of affected individuals develop a high–intraocular pressure (high-IOP) glaucoma associated with severe optic nerve disease. Although the elevation of IOP is likely to result from abnormal development of the anterior structures of the eye, a direct correlation between the severity of the anterior segment dysgenesis and the incidence of glaucoma has not been observed. Presumably, the structures that are involved in the elevation of IOP in these patients are not readily visible clinically. *PITX2* is a bicoid homeobox transcription factor that plays an important role in ocular development.<sup>18</sup> Mutations responsible for Rieger’s syndrome are LOF mutations and missense changes that interfere with critical protein domains. Interestingly, among family members carrying the same mutations, there can be extensive variation in the severity of the phenotype. The underlying mechanism responsible for this phenotypic variability is not known.

*FOXC1*, a member of the forkhead family of regulatory proteins, is located on chromosome 6p25. Mutations in this gene are associated with iris hypoplasia and glaucoma, as well as cardiovascular developmental abnormalities.<sup>17</sup> *FOXC1* gene dosage is important for normal function, as both deletions and duplications can result in abnormal phenotypes. The importance of the *FOXC1* gene in ocular development is demonstrated by a mouse knockout model that lacks the *FOXC1* gene product and has

abnormal development of the anterior segment of the eye.<sup>19</sup> Various anterior segment structures are abnormally formed in the *FOXC1*-deficient mouse, including the iris and Schlemm's canal.<sup>20</sup>

*PAX6* is a member of the paired box homeodomain proteins and mutations in this gene have been reported to cause aniridia, Peters' anomaly, and anterior stromal keratitis.<sup>21</sup> Aniridia and Peters' anomaly are both associated with glaucoma, presumably as a result of abnormal development of aqueous humor drainage structures.<sup>22</sup>

## PRIMARY OPEN-ANGLE GLAUCOMA: JUVENILE ONSET

Juvenile POAG is a rare disorder that develops during the first two decades of life. Affected individuals typically present with high IOP, which frequently requires surgical therapy. Juvenile glaucoma can be inherited as an autosomal dominant trait. Large pedigrees used for genetic linkage studies led to the identification of the *MYOC* gene, coding for myocilin as a causative gene.<sup>23</sup> Some mutations in this gene also cause of adult-onset POAG, in particular the GLN368X nonsense mutation.<sup>24</sup> The role of myocilin in glaucoma development is not completely understood; however, studies have indicated that mutant forms of the protein are retained in the cellular endoplasmic reticulum, preventing normal function of the cell and ultimately causing cell death.<sup>25</sup> Studies of patients who have genetic abnormalities resulting in a reduction of myocilin suggest that mutations in the gene cause gain of function or a dominant negative effect rather than LOF or haploinsufficiency.<sup>26–28</sup>

The protein contains several important functional domains, including a region with strong homology to the olfactomedin family of proteins. Although the function of the olfactomedin domain in myocilin is unknown, nearly all the mutations associated with glaucoma occur in this region.<sup>29</sup>

Only 10%–20% of patients with juvenile POAG have mutations in the *MYOC* gene. Using large pedigrees without *MYOC* mutations for genetic linkage studies, two additional juvenile POAG loci have been identified at chromosomes 9q and 20q.<sup>30</sup>

## PIGMENT DISPERSION SYNDROME AND GLAUCOMA

Pigment dispersion syndrome, a common disorder in young adults, is associated with the development of pigmentary glaucoma. Studies have shown that up to 2%–4% of Caucasian Americans 20–40 years of age may be affected by this disorder with characteristic features that include loss of iris contour and loss of pigment granules from the iris. The released pigment is deposited on the structures of the anterior segment of the eye, which include the trabecular meshwork. Although generally it is accepted that the dispersed iris pigment contributes to the development of glaucoma in affected individuals, the pathogenesis of pigmentary glaucoma remains unknown.

In humans, pigment dispersion can be inherited as an autosomal dominant trait, which suggests that specific gene defects may be responsible. One locus for this syndrome has been found on 7q35–q36,<sup>31</sup> but the responsible gene has yet to be isolated. The high prevalence of this condition indicates that more than one gene may be responsible for this disorder. Two genes that contribute to a form of pigment dispersion syndrome and glaucoma in the DBA/2J mouse have been identified.<sup>32</sup> These genes, *TYRP1* and *GNPMB*, are involved in pigmentation and melanosome metabolism and do not appear to contribute to the disease in humans.<sup>33</sup>

## ADULT-ONSET PRIMARY OPEN-ANGLE GLAUCOMA

Adult-onset POAG is a common disorder with complex inheritance. The prevalence of POAG in first-degree relatives of affected patients has been documented to be as high as 7–10 times that of the general population.<sup>34</sup> Using family-based linkage approaches, three genes have been identified as factors that can contribute to POAG: (1) certain mutations in *MYOC* (GLC1A), which can cause high-tension adult-onset open-angle glaucoma<sup>24</sup>; (2) a missense mutation in *OPTN* (GLC1E) coding for optineurin, which can cause familial low-tension glaucoma (see below)<sup>35,36</sup>; and *WDR36* (GLC1G) mutations, which may influence disease severity but do not appear to be causative.<sup>37,38</sup>

Genome-wide association studies (GWAS) have successfully identified 16 genes and loci statistically associated with POAG:

- *CAV1/CAV2*.<sup>39,40</sup>
- *CDKN2B-AS1*.<sup>41–43</sup>
- *TMCO1*.<sup>42,44</sup>
- *SIX1/SIX6*.<sup>42,43</sup>
- *8q22*.<sup>43</sup>
- *ABCA1*.<sup>45,46</sup>
- *AFAP1*.<sup>45</sup>
- *GMD5*.<sup>45</sup>
- *PMM2*.<sup>46</sup>
- *FNDC3B*.<sup>47</sup>
- *TGFBR3*.<sup>48</sup>
- *ARHGEF12*.<sup>49</sup>
- *GAS7*.<sup>50</sup>
- *FOXC1*.<sup>50</sup>
- *ATXN2*.<sup>50</sup>
- *TXNRD2*.<sup>50</sup>

The proteins encoded by these POAG-associated genes are beginning to identify biological processes and pathways that underlie disease development, including autophagy (*GMD5*, *PMM2*), ocular development (*SIX6*, *FOXC1*), lipid metabolism (*CAV1*, *ABCA1*, *ARHGEF12*), and mitochondrial function (*TXNRD2*). More research is needed to fully define the genetic architecture of POAG. In addition to the contributions of these susceptibility alleles, the complex genetic architecture of POAG is likely to include gene–gene and gene–environment interactions and epigenetic effects.<sup>51</sup>

## NORMAL-TENSION GLAUCOMA

Familial normal-tension glaucoma (NTG) can be caused by a missense mutation (Glutamine50Lysine) in *OPTN*, coding for optineurin.<sup>35,36</sup> Optineurin has important roles in autophagy and in the tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) signaling pathway. Both TNF- $\alpha$  and autophagy can impact apoptosis in retinal ganglion cells in patients with glaucoma.<sup>52–55</sup> Interestingly, a duplication of the *TBK1* gene, which codes for Tank1-binding protein, influences optineurin activity and also causes familial NTG.<sup>56</sup> Mutations in both *OPTN* and *TBK1* can also cause familial amyotrophic lateral sclerosis (ALS).<sup>57</sup> and a recent GWAS identified significant POAG association with *ATXN2*, another gene related to ALS risk.<sup>50</sup>

GWAS have identified *CDKN2B-AS* and a genomic region on 8q22 as risk factors for NTG.<sup>43</sup> Both *CDKN2B-AS* and the 8q22 region appear to impact TGF- $\beta$  signaling. The 8q22 region includes an enhancer with strong activity in choroid plexus and nonpigmented ciliary body epithelium, suggesting that this region could contribute to variation in cerebral spinal fluid pressure observed in NTG.<sup>58</sup>

## EXFOLIATION SYNDROME AND GLAUCOMA

Exfoliation is common in certain geographical regions, including Scandinavia, Russia, Nova Scotia (Canada), Scotland, northeastern United States, Saudi Arabia, and Greece, and among the Bantu population in Africa; the disease has a low prevalence in the Inuit population, Germany, the United Kingdom, and southern United States. The high prevalence of the condition in certain regions suggests a genetic founder effect, and this finding supports a genetic etiology. A GWAS conducted in Iceland initially identified *LOXL1*, coding for lysyl oxidase-like protein 1, as a genetic risk factor for pseudo-exfoliation syndrome. *LOXL1* is an enzyme necessary for elastogenesis and elastic fiber maintenance.<sup>59</sup> Subsequently, *LOXL1* has been associated with exfoliation syndrome worldwide; however, although the risk alleles are present in over 90% of cases, they have also been observed to be prevalent in controls (up to 85%) suggesting that *LOXL1* is necessary but not sufficient for disease development and that other genetic and/or environmental factors also contribute to disease risk.<sup>60</sup> A subsequent GWAS for exfoliation syndrome has identified association with *CACNA1A*,<sup>61</sup> coding for a protein that forms a calcium channel. In addition to genetic factors, environmental risk factors also significantly contribute to exfoliation syndrome, especially residence in northern latitudes.<sup>60,62,63</sup>

## ANGLE-CLOSURE GLAUCOMA

Angle-closure glaucoma is highly heritable, suggesting that specific genes can contribute to the condition.<sup>64</sup> Frequently, angle-closure glaucoma is

associated with hyperopia or nanophthalmos. One gene for nanophthalmos has been located on chromosome 11.<sup>65</sup> Also located on chromosome 11, defects in the *MFRP* gene have been shown to be responsible for some cases of nanophthalmos.<sup>66</sup> This gene is selectively expressed in the eye and encodes a protein with homology to Tollid proteases and the Wnt-binding domain of the Frizzled transmembrane receptors. These proteins are involved in signaling pathways, and *MFRP* appears to be primarily devoted to regulating axial length of the eye.

GWAS for angle-closure glaucoma have also been completed and have identified eight genetic risk loci:

- PLEKHA7.
- COL11A1.
- PCMTD1-ST18.
- EPDR1.
- CHAT.
- GLIS3.
- FERMT2.
- DPM2-FAM102A.<sup>67,68</sup>

## Evidence-Based Medicine in Glaucoma

10.34

Henry D. Jampel, Guadalupe Villarreal, Jr.

**Definition:** Evidence-based medicine is the use of the highest-quality medical data currently available to assist in clinical decision making.

## Key Features

- Five levels of evidence: the Oxford Centre for Evidence-Based Medicine 2011 Levels of Evidence<sup>1</sup> proposes the following hierarchy for levels of evidence:
  - Systematic review of randomized controlled trials.
  - Randomized controlled trials.
  - Cohort study.
  - Case series.
  - Mechanistic reasoning.

## INTRODUCTION

The practice of medicine will always be a combination of science and art. We learn the artistic aspects from our teachers and from our own experiences. The scientific parts of medicine involve using evidence that has been gathered through the rigorous observations of others in the course of clinical research.

Physicians have always attempted to use the best available medical knowledge to make decisions about the care of their patients. During the early part of the twentieth century, the best available knowledge mainly consisted of techniques and approaches that had been passed on from other physicians. These techniques and approaches were rarely scrutinized for effectiveness in a rigorous and systematic way. Most of medical practice was eminence based (“driven by really charismatic and thoughtful, probably, to some degree, leaders in medicine”),<sup>2</sup> rather than evidence based. A movement toward improving the quality of medical practice with well-designed clinical trials began in the 1970s–1980s.<sup>3–5</sup>

The term *evidence-based medicine* (EBM) gained popularity in the 1990s. Several authors have offered definitions for the term. Sackett defines EBM as the “conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients.”<sup>6</sup> Most agree that the first step in practicing EBM is to recognize a clinical problem or question that needs to be answered. For example, one might ask, “Does medical therapy work to prevent glaucoma in patients with elevated intraocular pressure (IOP)?” The next step is to find the available best scientific evidence that addresses the problem or question. When there are conflicting data, it can be difficult to draw an appropriate conclusion if all of the data are weighed equally. To find the most reliable answer to a clinical question, it helps to focus on the higher-quality sources of evidence, such as appropriately conducted and analyzed randomized clinical trials (RCTs) and case-control studies.<sup>7,8</sup> However, in all instances, the reader must be aware of the inherent weaknesses and strengths of these studies.

## TOOLS OF EVIDENCE-BASED MEDICINE

Published reports of clinical experience are the foundation of EBM. A common scenario for the development of increasingly stronger evidence is for a clinician to formulate an impression about a disease process or an intervention and then review and publish his or her experience as a retrospective case series. This, then, leads to a prospective study that can be observational or interventional. Finally, promising results from a non-randomized prospective study can lead to an RCT.

## Randomized Clinical Trials

An RCT is a study in which participants are randomly assigned to one or more groups. The process of randomization eliminates bias in the allocation of subjects to one treatment or another.<sup>9</sup> The results of RCTs are often considered the highest-quality evidence and hence are the backbone of EBM. For instance, the Cochrane Collaboration, a leading proponent of EBM, largely limits its reviews to the analysis of RCTs.

A properly designed RCT has the potential to demonstrate a cause-and-effect relationship between a treatment and a specific patient response. For the results from an RCT to be useful, several conditions need to be met. The hypothesis of the trial has to be narrow in scope and clinically relevant. The appropriate number of patients has to be included in the study to ensure that a negative result is truly negative. Biases in the study have to be minimized. The Ocular Hypertension Treatment Study (OHTS)<sup>10</sup> is an example of an RCT that was sufficiently focused, appropriately powered, and sufficiently free of bias to answer the question “Does medical therapy work to prevent glaucoma in patients with elevated intraocular pressure?”

Although considered a robust study design, RCTs vary widely in their quality, depending on their sample size, inclusion and exclusion criteria, rigor in randomization, masking of observers and subjects, loss to follow-up, and data presentation. Adherence to the CONSORT (Consolidated Standards of Reporting Trials) guidelines for reporting clinical trials ensures a minimal quality of an RCT,<sup>11</sup> but even the best RCTs have some inherent weaknesses.<sup>6</sup> For instance, inclusion and exclusion criteria associated with the studies may result in findings that are not applicable to a patient who would not have qualified for the study.<sup>12</sup> For example, the OHTS specifically did not address the question of whether treatment was advantageous for patients with IOP of 21–24 mm Hg.<sup>13</sup> In addition, RCTs may not uncover all of the possible problems and adverse events associated with a particular therapy. An example of this can be found in the Collaborative Initial Glaucoma Treatment Study (CIGTS), a multicenter RCT in which individuals with newly diagnosed open-angle glaucoma were randomized to initial medical or surgical treatment.<sup>14</sup> The number of subjects who underwent trabeculectomy in the CIGTS, although sufficient to compare the success of initial medical treatment versus initial surgical treatment of newly diagnosed open-angle glaucoma, precluded obtaining useful information about the rare, but serious, complication of bleb-related infection.

Another disadvantage of RCTs is that depending on the endpoint, they may take a long time to reach completion.<sup>15</sup> When the time frame of an RCT is several years or more, it is not unusual for the therapies that are being evaluated to have been replaced by seemingly better treatments by the time the findings of the trial are published. For example, the Glaucoma Laser Trial (GLT) compared argon laser trabeculoplasty with medical therapy in the treatment of patients with newly diagnosed glaucoma and found that laser and medications to be equally effective.<sup>16</sup> However, the medical therapies available at the time included only those with timolol, epinephrine, pilocarpine, and acetazolamide pills. Some have questioned the applicability of the study today, with the availability of prostaglandins, alpha-agonists, and topical carbonic anhydrase inhibitors. Finally, the literature is replete with RCTs that did not include enough participants to determine the answer to the posed clinical question.

## Meta-Analyses and Systematic Reviews

When multiple RCTs have been conducted on a given topic, a meta-analysis can be employed. In a meta-analysis, statistical techniques are used to measure and compare the outcomes of multiple studies. By combining the outcomes of multiple studies, the overall sample size and statistical power are increased.<sup>17</sup> Meta-analyses are particularly useful when there

**Fig. 10.34.1** Systematic reviews often include a forest plot, which shows the variation in trial results and estimates the cumulative result of the included trials. Shown in the figure are the results of a hypothetical meta-analysis of three studies (A–C) looking at the relationship between use of topical glaucoma medications and risk of developing glaucoma. The results are shown in terms of estimated relative risk of developing glaucoma. The relative risk associated with each study is shown with a point estimate; the horizontal line on which the point lies represents the confidence interval. Because the use of topical medications is expected to reduce the risk of glaucoma, the relative risk should be less than 1.0. Study B yielded a relative risk greater than 1.0, which indicates that using topical drops increases the risk of glaucoma. This finding in study B does not agree with the results from studies A and C, which show that using topical drops does decrease the risk of glaucoma. The confidence intervals are an indication of the precision of each study. Study A has the narrowest confidence interval (highest precision) and study C has the widest confidence interval (lowest precision). The combined results of the three studies are indicated by the diamond at the bottom of the chart. The side points of the diamond represent the confidence interval. The upper and lower points of the diamond represent the point estimate of the relative risk for the combined studies. (From Greenberg R, Daniels S, Flanders W, et al. *Medical epidemiology*, 4th ed. New York: McGraw-Hill Medical, 2004.)

are small clinical trials that are inconclusive, perhaps because of size, and when different RCTs come to different conclusions. The averages of the study results are often weighted, placing more emphasis on larger studies. Forest plots are a convenient way of summarizing the statistical analyses performed on the studies used for the meta-analyses (Fig. 10.34.1).<sup>18</sup> Meta-analyses can be useful for reducing the biases and improving the precision that is associated with RCTs.<sup>8</sup>

An example of a meta-analysis in glaucoma therapy is the study by Maier et al.,<sup>13</sup> which addressed whether lowering of IOP delays the progression of visual field defects in patients with open-angle glaucoma. This study is of particular note because it was published in the *British Medical Journal*, not in an ophthalmology journal. It gives us insight into the limited conclusions that nonophthalmologists are willing to draw from our ophthalmological data. Maier et al. were willing to only conclude that lowering IOP in patients with ocular hypertension or manifest glaucoma lowers the risk of visual field loss and has unclear effects in patients with normal-tension glaucoma, whereas the glaucoma community has drawn more widespread conclusions from these data regarding IOP lowering in glaucoma.

Another meta-analysis compared the effectiveness and adverse effects of adding a second IOP-lowering agent to an eye already being treated with a topical prostaglandin.<sup>19</sup> The authors of that meta-analysis appropriately followed established guidelines (Quality of Reporting of Meta-analyses [QUORUM]) for the performance of a meta-analysis, used predetermined inclusion and exclusion criteria for selecting trials, and reported on how well the included studies met the quality criterion. They found that the effectiveness of the three classes of medications was similar but that they each had different side-effect profiles. Li et al.<sup>20</sup> performed a systematic review and network meta-analysis of 114 RCTs comparing the effectiveness of first-line IOP-lowering eyedrops in patients with ocular hypertension or primary open-angle glaucoma (POAG). Those authors found that prostaglandin medications were the most efficacious class, with within-class differences being small and probably not clinically meaningful.<sup>20</sup> Mean reductions in IOP (mm Hg) at 3 months compared with that in placebo group were as follows: bimatoprost (5.61), latanoprost (4.85), travoprost (4.83), levobunolol (4.51), tafluprost (4.37), timolol (3.70), brimonidine (3.59), carteolol (3.44), levobetaxolol (2.56), apraclonidine (2.52), dorzolamide (2.49), brinzolamide (2.42), betaxolol (2.24), and unoprostone (1.91).<sup>20</sup>

Although meta-analyses can put our clinical decision making on a firmer footing, they have their own limitations. First, bias and errors associated with the included studies may become magnified in the meta-analysis. Second, they often do not include negative studies because these studies may never have been published. When this is the case, the meta-analysis will yield a result that is more positive than the aggregate of all data, published and unpublished. Thus, when evaluating meta-analyses, it is important to ask what the authors did to minimize potential bias.

For most clinical questions, multiple, high-quality RCTs have not been conducted, and it is not possible to carry out a true meta-analysis. In these instances, a systematic review of the literature can be conducted. Systematic reviews include a well-defined and carefully executed review of the literature, an algorithm for determining which types of studies to include in the review, and an assessment of the quality of the manuscripts reviewed. Because studies with different designs are included, the authors generally cannot make more than qualitative statements about the answers provided by the aggregate of studies.

The Cochrane Collaboration has been at the forefront of performing meta-analyses of RCTs. In the area of glaucoma, the Cochrane Collaboration has reported on optic nerve head and fiber layer imaging for diagnosing glaucoma,<sup>21</sup> laser peripheral iridoplasty for angle closure,<sup>22</sup> laser trabeculoplasty for open-angle glaucoma,<sup>23</sup> 5-fluorouracil (5-FU) for glaucoma surgery,<sup>24</sup> intraoperative mitomycin C (MMC) for glaucoma surgery,<sup>25</sup> fornix-based versus limbal-based conjunctival trabeculectomy flaps,<sup>26</sup> needling for encapsulated blebs,<sup>27</sup> interventions for late trabeculectomy bleb leak,<sup>28</sup> combined surgery versus cataract surgery alone for eyes with cataract and glaucoma,<sup>29</sup> and medical versus surgical interventions for open-angle glaucoma.<sup>30</sup>

One organization in the United States that provides funding for systematic reviews is the Agency for Health Research and Quality (AHRQ). Within the field of ophthalmology, the AHRQ has funded systematic reviews in anesthesia for cataract surgery,<sup>31</sup> treatments for open-angle glaucoma,<sup>32</sup> surgical management of coexisting cataract and glaucoma,<sup>33</sup> and the effects of omega-3 fatty acids on eye health.<sup>34</sup> As part of the process of formulating its Preferred Practice Patterns,<sup>35</sup> the panel of experts chosen by the American Academy of Ophthalmology (AAO) carefully reviews the literature and assigns each study a quality rating and an importance to clinical care rating. The AAO, through its Ophthalmic Technology Assessments, has published systematic reviews in glaucoma, such as the effect of phacoemulsification on IOP in patients with glaucoma.<sup>36</sup>

## Other Study Designs

Clinicians who base their decisions solely on the results of RCTs, meta-analyses, and systematic reviews will be left with many situations for which they will have no guidance. As can be found upon opening any clinical ophthalmology journal, the bulk of articles rely on study designs generally considered less rigorous. These study designs include case reports, case series, cross-sectional studies, cohort studies, and case-control studies. These studies are still useful as long as the reader is aware of their limitations.

## Case Reports

Case reports are descriptions of individual patients with new diseases, conditions of interest, or of interventions in individual patients. Their main value is to encourage further investigation of the disease or intervention.

Case series contain multiple case reports and may provide summary statistics concerning results. They provide a stronger impetus to further study compared with a single case report.

### Cross-Sectional Studies

Cross-sectional studies are used to determine the prevalence of a disease or problem and are also commonly used to evaluate diagnostic tests. The Blue Mountains Eye Study used a cross-sectional design to determine the prevalence of open-angle glaucoma and ocular hypertension in the Australian population. They found that the prevalence of open-angle glaucoma was 3% and that of ocular hypertension was 3.7%.<sup>37</sup> A disadvantage of this study design is that its findings cannot be used to determine temporal sequence or cause and effect.<sup>38</sup>

### Case-Control Studies

Case-control studies are used to determine risk factors for a disease or a complication. They are particularly useful in situations where a disease or complication is rare. Individuals with a given condition (cases) are carefully matched to individuals who do not have the condition (controls). The cases and controls are then compared in terms of their previous exposure to possible risk factors. An odds ratio is calculated to quantify the higher likelihood of cases having been exposed compared with the controls.<sup>39</sup> For example, Jampel et al.<sup>40</sup> used a case-control study to look at late-onset infection after glaucoma filtration surgery and found that risk factors for infection included full-thickness procedures, filtration surgery performed without cataract surgery, MMC use, and chronic postoperative use of antibiotics. It should be emphasized that case-control studies can identify associations but cannot prove cause and effect. One of the most important pitfalls of case-control studies is the inappropriate selection of controls.

### Cohort Study

In a cohort study, a group of individuals is followed up over time. Cohort studies can be prospective or retrospective and are used to study the natural history and incidence of diseases. For instance, as a part of the Blue Mountains Eye Study, Chandrasekaran et al.<sup>41</sup> used a cohort study to show that eyes with elevated IOP at presentation treated with topical glaucoma medications had a twofold increased risk of 5-year incident nuclear cataract development.

### Other Limitations

The validity of the results of clinical studies can be limited by selection bias and information bias.<sup>42</sup>

#### Selection Bias

Selection bias occurs when the investigator's methods of obtaining subjects for the study affects the relationship between risk factors and outcomes. For instance, patients who are referred to an investigator as potential study subjects and who agree to participate in a study may not be representative of all individuals in the population of interest. The investigator's inclusion and exclusion criteria can also add to selection bias. Loss to follow-up is another significant contributor to selection bias.<sup>17</sup>

#### Information Bias

Information bias results from inaccurate measurement of risk factor or disease presence. When information bias results from errors in the subject's ability to report risk factors and exposures accurately, it is called *recall bias*. For example, when asked about family history of glaucoma, individuals already diagnosed with glaucoma may be more likely to search their memory for distant relatives who could possibly have had glaucoma compared with individuals who believe their eyes are healthy. This kind of recall bias would affect the results of a study looking at the role of family history as a risk factor for glaucoma.

## EVALUATION OF DIAGNOSTIC TESTING IN GLAUCOMA

Diagnostic testing in glaucoma serves two purposes: first, to assess whether glaucoma is present and, second, to determine if there has been progression of disease. There is no consensus about what constitutes progression, and developing a consensus is a major focus for clinical researchers. The evaluation of diagnostic testing in determining progression will therefore not be discussed further, except to make the following generalizations: Progression can be determined by (1) a change in structure or function; (2)

a change that signifies progression must exceed the variability inherent in performing a test repeatedly over time; and (3) the ability of a diagnostic modality to detect progression is dependent on the severity of the disease (e.g., it is generally assumed that at the later stages of disease, evaluation of perimetry is more valuable than evaluation of the optic disc or retinal nerve fiber layer). The emphasis in this section will, instead, be on the use of diagnostic tests to diagnose glaucoma, that is, to separate persons with disease from persons without disease.

Using diagnostic tests to detect glaucoma occurs in two settings—(1) in the community to “screen” and (2) in the doctor's office in patients deemed to be at risk for glaucoma, such as those with elevated IOP or a family history of glaucoma. Community screening for glaucoma is important because population-based studies have repeatedly demonstrated that a large proportion of individuals with glaucoma are undiagnosed. These are two distinct situations that call for different diagnostic tests.

The literature on diagnostic tests is peppered with technical terms, such as *sensitivity*, *specificity*, *positive predictive value*, *negative predictive value*, *likelihood ratios*, and *receiver operating curves* (see below). A brief review of some of these concepts is presented below.

Every diagnostic test is designed to determine whether a patient has a distinct condition or disease. Although the test may yield data points that lie within a wide range of values, the test results are ultimately interpreted as being either positive or negative for the disease of interest. The defining value at which the test result changes from positive to negative is called the *cutoff point*. Before diagnostic test performance can be quantified, some definitions are necessary. The sensitivity of a test is defined as the percentage of patients with positive test results who have the disease (sensitivity = patients with positive results and disease/total number of patients with disease).<sup>43</sup> The specificity of a test is defined as the percentage of patients with negative test results in the group of patients who do not have the disease (specificity = patients with negative results and no disease/total number of patients without disease).<sup>43</sup>

Sensitivity and specificity are affected by the choice of the cutoff point for the test. A high cutoff point is associated with higher test specificity and lower sensitivity, whereas a lower cutoff point is associated with higher test sensitivity and lower specificity. The performance of a diagnostic test can be estimated by plotting sensitivity against (1 – specificity) using values generated over a range of cutoff points. The resulting plot is called a *receiver operating characteristic (ROC) curve* (Fig. 10.34.2).<sup>17</sup> The area under the curve (AUC) for a test or device is a measure of its utility. An AUC of 1.0 is perfect, and a test with an AUC of 0.5 has no diagnostic utility.

**Fig. 10.34.2** A receiver operating characteristic (ROC) curve. The area under the ROC curve is 1 for an ideal or perfect diagnostic test. The area under the ROC curve is 0.5 for a test that does not distinguish between patients with or without the disease. In this figure, test A has better diagnostic value than curve B. (From Greenberg R, Daniels S, Flanders W, et al. Medical epidemiology, 4th ed. New York: McGraw-Hill Medical, 2004.)

The likelihood ratio (LR) is the likelihood that a given test result would be expected in a patient with a disease compared with the likelihood that the same result would be expected in a patient without the disease. The LR, like the ROC curve, is used to assess how good a diagnostic test is. The LR for a positive test result is (sensitivity)/(1 – specificity) and for a negative test result is (1 – sensitivity)/specificity. The LR is less likely to change with disease prevalence compared with sensitivity and specificity. Furthermore, the LR can be used, as illustrated in the example that follows, to calculate the post-test probability of a patient having the disorder in question.

The way that the LR is used is as follows: First, the LR is calculated as (sensitivity/1 – specificity). Second, the pretest odds of the condition being present, which is given by the formula: (pretest probability)/(1 – pretest probability), are calculated. Third, the post-test odds, the product of the pretest odds and the LR, are calculated. Finally, the post-test probability is calculated by dividing the post-test odds by (1 + post-test odds).

As an example, suppose you have a test with a sensitivity of 80% and a specificity of 90% for the detection of glaucoma: the LR for your test is 8 (80% ÷ 10%). Assume that the prevalence of glaucoma in your study population is 10%: the pretest odds ratio of a person having glaucoma is 1/9 (10% ÷ 90%). The post-test odds that a person testing positive has glaucoma are then 8 × 1/9, or 8/9. The post-test probability of the patient having the disease is (8/9 ÷ 17/9) or 8/17 (47%). A nomogram is available that allows a direct conversion from pretest to post-test probability if one knows the likelihood ratio (Fig. 10.34.3).

Many studies reported in the recent literature have described the utility of vision tests and imaging devices for diagnosing glaucoma. When designing a diagnostic accuracy study, it is important to determine the

purpose of the diagnostic test.<sup>44</sup> As one of the roles of spectral-domain optical coherence tomography (SD-OCT) is to determine whether those at risk for glaucoma have structural damage, design of a diagnostic accuracy study for OCT would therefore focus on evaluating glaucoma suspects.<sup>44</sup> An example is the study by Banister et al.,<sup>45</sup> which was a multicenter, prospective study performed in the United Kingdom comparing the diagnostic performance of Heidelberg Retina Tomograph III (HRT; Heidelberg Engineering, Germany) with Moorfields regression analysis (MRA) and glaucoma probability score (GPS) classification algorithms, scanning laser polarimetry (GDx; Carl Zeiss Meditec, Dublin, CA), and Spectralis SD-OCT (Heidelberg Engineering) in newly referred glaucoma suspects. A total of 943 patients were included in the analysis, 17% of whom had been diagnosed with glaucoma in at least one eye based on clinical assessment and automated perimetry. Amongst the four imaging test algorithms, HRT MRA had the highest sensitivity (87%) with the lowest specificity (64%), and GDx had the lowest sensitivity (35%) with the highest specificity (97%). HRT GPS and Spectralis SD-OCT had intermediate levels of sensitivity (82% and 77%, respectively) and specificity (68% and 79%, respectively).<sup>45</sup> On the basis of these results, the authors of the study concluded that automated imaging tests remain an adjunct to clinical assessment and perimetry and that reliance solely on imaging technologies is not advisable.<sup>45</sup>

In evaluating the usefulness of a diagnostic test, the reader must always keep the following points in mind. First, it is logical to evaluate a new diagnostic technique in a clinical setting, but one must not extrapolate the performance of a diagnostic test in a clinic to its performance as a screening test in the community. As a rule, specificity is lower in the community than in the clinic. Second, the amount of damage in the glaucoma group greatly influences the performance of any test. It is easier for a test to distinguish between severe disease and the normal state than to distinguish between early disease and the normal state. Third, the defining criteria for the diagnosis of glaucoma can affect the performance of the test. The ability of an optic disc imager to distinguish the normal state from glaucoma may vary, depending on whether the diagnosis of glaucoma was made on the basis of optic disc findings, visual field findings, or both.

Above and beyond the preceding comments, conducting, reporting, and interpreting studies on diagnostic accuracy can be difficult. The Standards for Reporting of Diagnostic Accuracy (STARD) initiative was established to improve the quality of studies of diagnostic accuracy. One result of this initiative is a checklist of 25 items that should be included in a diagnostic accuracy study. Four publications suggested that the adherence to the STARD criteria by published studies of imaging devices and automated perimetry for the diagnosis of glaucoma is suboptimal and warrants improvement.<sup>46–49</sup> Readers must interpret the reports on diagnostic tests with caution.

## EXAMPLES OF EVIDENCE-BASED MEDICINE IN GLAUCOMA THERAPY

Several clinical trials have been conducted over the years to evaluate the treatment of glaucoma (Boxes 10.34.1 through 10.34.9). Here, examples of important issues in glaucoma management and several of the relevant clinical trials that influence how we treat glaucoma today are highlighted.

A critical question that is confronted daily is “Does medical reduction of IOP prevent or delay the onset of optic nerve damage and visual field loss in patients with ocular hypertension?” Prior to the OHTS, three small RCTs had failed to demonstrate a beneficial effect of IOP lowering in subjects with ocular hypertension.<sup>50–52</sup> However, the OHTS convincingly demonstrated that medical reduction of IOP could reduce the incidence of glaucoma from approximately 10% to 5% over a period of 5 years (see Box 10.34.1).<sup>10,53–55</sup> Unlike the OHTS, the European Glaucoma Prevention Trial failed to find an effect of medical lowering of IOP on the rate of incident glaucoma.<sup>56</sup> Possible explanations for the lack of effect in this trial are eloquently enumerated in a letter to the editor.<sup>57</sup> The OHTS also determined the risk factors predisposing to the conversion of subjects to glaucoma damage. This determination has formed the basis for glaucoma risk calculators.<sup>58,59</sup> A meta-analysis of trials of medical treatment of elevated IOP reached the same conclusion as that by the OHTS.<sup>13</sup>

A crucial related question is whether lowering IOP in patients who already have glaucoma damage could decrease the likelihood of worsening of damage. This question was addressed in the Early Manifest Glaucoma Trial (EMGT) (see Box 10.34.2).<sup>60,61</sup> Patients with newly diagnosed, early glaucoma damage were randomized to treatment with betaxolol eyedrops and laser trabeculoplasty or observation. This protocol differed from other treatment trials in that no specific amount of IOP lowering

**Fig. 10.34.3** Nomogram for converting pretest probabilities to post-test probabilities for a diagnostic test result with a given likelihood ratio. (Reproduced with permission from the Oxford Centre for Evidence-Based Medicine. Available at: <http://www.cebm.net>.)

**BOX 10.34.1 Ocular Hypertension Treatment Study (OHTS)**<sup>10,53–55</sup>

**Clinical question:** Does medical reduction of IOP prevent or delay the onset of optic nerve damage and visual field loss in patients with ocular hypertension?

**Study type:** Multicenter randomized clinical trial

**Number of patients:** 1636

**Duration:** Patients followed up for a minimum of 5 years

**Eligibility:** Men and nonpregnant women with normal visual fields and optic discs, between the ages of 40 and 80, with IOP  $\geq 24$  mm Hg but  $\leq 32$  mm Hg in one eye and IOP  $\geq 21$  mm Hg but  $\leq 32$  mm Hg in the fellow eye

**Methods:** Patients were randomized to observation or treatment with topical ocular hypotensive medications. Patients receiving treatment had target IOP that was a minimum of 20% below baseline and that was also  $\leq 24$  mm Hg. Patients were followed up every 6 months. Proportional hazards models were used to identify risk factors for POAG

**Results:** After 60 months, the probability of developing POAG was 4.4% in the group receiving medication and 9.5% in the group that did not receive medication

**Conclusions:** Patients receiving topical medications had a lower risk of developing POAG than patients receiving no medication

*IOP, Intraocular pressure; POAG, primary open-angle glaucoma.*

**BOX 10.34.2 Early Manifest Glaucoma Trial (EMGT)**<sup>60,61</sup>

**Clinical question:** How is the progression of OAG affected by immediate IOP-lowering therapy when compared with late IOP-lowering therapy or no treatment?

**Study type:** Randomized clinical trial

**Number of patients:** 255

**Duration:** Patients were followed for a minimum of 4 years

**Eligibility:** Swedish men and women between the ages of 50 and 80 years with newly detected and untreated OAG and repeatable Humphrey visual field defects

**Methods:** Patients were randomized to observation or treatment with topical betaxolol and ALT. Visual field progression was determined using HVF 30-2 fields and by evaluating three consecutive glaucoma change probability maps. Optic disc progression was determined using disc photos and flicker chronoscopy

**Results:** After 6 years, 53% of patients had experienced disc and field progression. In a multivariate analysis, untreated patients had twice the glaucoma progression risk of patients who received treatment

**Conclusions:** Untreated patients had twice the glaucoma progression risk of patients who received treatment

*ALT, Argon laser trabeculoplasty; IOP, intraocular pressure; OAG, open-angle glaucoma.*

was required. Subjects randomized to IOP-lowering treatment were less likely to sustain further glaucoma damage compared with the untreated group. A startling finding of the EMGT was the rate of progression in both the untreated and treated groups. At 6 years, 45% of treated patients and 62% of untreated patients had progressed to glaucoma damage.<sup>61</sup> Why the rate of progression was so much higher than that estimated in other studies is unclear, but it is not simply the result of a looser definition of progression.<sup>62</sup> Similar to the OHTS, risk factors for progression included exfoliation syndrome, older age, bilateral disease, higher baseline IOP, and worse mean deviation.

Additional RCTs have addressed the relative merits of different methods of lowering IOP. The Glaucoma Laser Trial (GLT) (see Box 10.34.3)<sup>16,63–65</sup> addressed the question of whether medical therapy or argon laser trabeculoplasty (ALT) was more effective at controlling IOP in patients with glaucoma.<sup>16</sup> Its authors concluded that ALT was at least as effective in the management of newly diagnosed glaucoma as medical therapy, but its conclusions were immediately called into question because of the perceived flaws in the study.<sup>66,67</sup> The GLT illustrates one of the hazards of prolonged clinical trials—the results becoming obsolete by the time the study is completed. The GLT permitted the use of currently available medications for lowering IOP, which were beta-blockers, adrenergic agents, miotics, and oral carbonic anhydrase inhibitors. Currently, a number of more effective

**BOX 10.34.3 Glaucoma Laser Trial (GLT) and Glaucoma Laser Trial Follow-Up Study (GLTFS)**<sup>16,63–65</sup>

**Clinical question:** Is ALT a safe and effective treatment for newly diagnosed POAG?

**Study type:** Randomized clinical trial

**Number of patients:** 271 (542 eyes)

**Duration:** Median follow-up of 7 years

**Eligibility:** Men and women 35 years of age or older with IOP of  $\geq 22$  mm Hg in each eye and glaucomatous optic nerve injury in at least one eye

**Methods:** One eye was randomized to laser treatment and the other eye to topical medication

**Results:** Eyes treated initially with ALT as opposed to medication had IOPs that were on average 1.2 mm Hg lower, had a 0.6 dB greater improvement in the visual field, and had a change in cup-to-disc area ratio that was 0.01 less than the change in cup-to-disc area ratio for eyes treated initially with medication

**Conclusions:** Patients treated initially with ALT had lower IOPs, better visual fields, and less glaucomatous optic nerve damage than patients treated initially with medications

*ALT, Argon laser trabeculoplasty; IOP, intraocular pressure; POAG, primary open-angle glaucoma.*

**BOX 10.34.4 Advanced Glaucoma Intervention Study (AGIS)**<sup>68–72</sup>

**Clinical question:** How are outcomes in OAG patients affected by the sequence of treatment with ALT and trabeculectomy?

**Study type:** Multicenter randomized clinical trial

**Number of patients:** 591 (789 eyes)

**Duration:** Patients followed up for a minimum of 4 years; study ongoing

**Eligibility:** Men and women between the ages of 35 and 80 years with POAG not controlled with medications

**Methods:** Eyes were randomized to receive either ALT followed by trabeculectomy 1 and trabeculectomy 2 (ATT sequence) or trabeculectomy 1 followed by ALT then trabeculectomy 2 (TAT sequence)

**Results:** In black patients, the average percent of eyes with VF loss was less in the ATT sequence than in the TAT sequence. In white patients, conversely, after 18 months the average percent of eyes with VF loss was less in the TAT sequence

**Conclusions:** Although race was not considered when the hypothesis of the study was generated, post hoc analysis suggests that long-term visual function outcomes were better for the ATT sequence in black patients and better for the TAT sequence in white patients

*ALT, Argon laser trabeculoplasty; POAG, primary open-angle glaucoma.*

**BOX 10.34.5 Collaborative Initial Glaucoma Treatment Study (CIGTS)**<sup>74–76</sup>

**Clinical question:** Are patients with OAG best managed with initial topical medication or by initial filtration surgery?

**Study type:** Multicenter randomized controlled clinical trial

**Number of patients:** 607

**Duration:** Patients were followed up for a minimum of 5 years

**Eligibility:** Men and women 25 years of age and older with OAG, IOP  $\geq 20$  mm Hg and visual field loss or glaucomatous optic nerve damage in one or both eyes

**Methods:** Patients were randomized to receive initial treatment with medications or trabeculectomy

**Results:** There was no significant difference in visual field loss between the two groups. Subjects randomized to trabeculectomy had more ocular symptoms during the first 2 years than those randomized to medications

**Conclusions:** Initial medical treatment and initial filtering surgery were both effective at preserving vision; there was a slight advantage for medications in terms of comfort

*IOP, Intraocular pressure; OAG, open-angle glaucoma.*

**BOX 10.34.6 The Fluorouracil Filtering Surgery Study (FFSS)<sup>79</sup>**

**Clinical question:** Does postoperative subconjunctival 5-FU increase the success of trabeculectomy in patients at risk for trabeculectomy failure?

**Study type:** Multicenter randomized clinical trial

**Number of patients:** 213

**Duration:** 5 years

**Eligibility:** Men and women with IOP >21 mm Hg in one or both eyes despite maximum-tolerated therapy and previous cataract surgery or failed trabeculectomy

**Methods:** Patients were randomized to trabeculectomy alone or trabeculectomy with postoperative subconjunctival 5-FU injections

**Results:** After 5 years, 51% of the eyes that received 5-FU and 74% of the eyes that did not receive 5-FU had failed trabeculectomies

**Conclusions:** Trabeculectomy success rates with 5-FU were improved over standard trabeculectomy success rates for 5 years

5-FU, 5-fluorouracil; IOP, intraocular pressure.

**BOX 10.34.7 The Tube Versus Trabeculectomy (TVT) Study<sup>84</sup>**

**Clinical question:** Is tube shunt surgery or trabeculectomy safer or more effective in eyes with prior ocular surgery?

**Study type:** Multicenter randomized clinical trial

**Number of patients:** 212 (145 reported on with 5 years of follow-up)

**Duration:** 5 years

**Eligibility:** Individuals between 18 and 85 years of age, with a history of previous trabeculectomy and/or cataract extraction with intraocular lens implantation, and intraocular pressure (IOP) between 18 and 40 mm Hg on maximum tolerated medical therapy.

**Methods:** Patients were randomized to receive either a Baerveldt 350 mm<sup>2</sup> aqueous drainage device or a trabeculectomy with mitomycin C 0.4 mg/ml for 4 minutes

**Results:** With failure defined as IOP >21 mm Hg or not reduced by 20%, IOP <5 mm Hg, reoperation for glaucoma, or loss of light perception vision, the failure rate was lower at 5 years in the tube group (30%) than in the trabeculectomy (47%) group ( $P = 0.002$ ).

**Conclusions:** In eyes with previous cataract surgery and/or trabeculectomy, Baerveldt aqueous drainage device implantation had a higher success rate than trabeculectomy with mitomycin C. One proviso is that although not statistically significant, eyes undergoing trabeculectomy had a lower intraocular pressure ( $12.6 \pm 5.9$  mm Hg) compared with eyes undergoing Baerveldt implantation ( $14.4 \pm 6.9$  mm Hg).

medications are available, and if the GLT is performed again today, its results may very well favor medical therapy.

The Advanced Glaucoma Intervention Study (AGIS) is one of the most frequently cited and discussed RCTs in glaucoma (see [Box 10.34.4](#)).<sup>68-72</sup> It sought to answer the question as to whether performing trabeculoplasty or trabeculectomy next in patients already on maximum medical treatment was the more effective approach for preserving vision. The answer to that question in the AGIS was that trabeculoplasty (followed by trabeculectomy, if necessary) and trabeculectomy (followed by trabeculoplasty if necessary) were equally effective. However, this conclusion has been overshadowed by analyses performed after dividing the subjects on the basis of race (black or white).<sup>68-70</sup> When this is done, it appears that overall vision preservation is better in black patients if trabeculoplasty is performed first and in white patients if trabeculectomy is performed first. However, there are those who question the validity of such “post hoc” analyses that were not planned for at the inception of the study. The AGIS data set has also been used to emphasize the importance of maintaining consistently low IOPs in patients with glaucoma<sup>71</sup> and the importance of IOP fluctuation<sup>73</sup> in glaucoma progression. The reader must realize that conclusions drawn from data and analyses that were not specifically designed for an RCT to address its specific aims cannot be given the same weight as the primary outcome data.

The CIGTS was another RCT comparing modalities of treating glaucoma (see [Box 10.34.5](#)).<sup>74-76</sup> In the CIGTS, subjects with newly diagnosed open-angle glaucoma were randomized to initial medical treatment or

**BOX 10.34.8 Five-Year Pooled Data Analysis of the Ahmed Baerveldt Comparison (ABC) Study and the Ahmed Versus Baerveldt (AVB) Study<sup>85-87</sup>**

**Clinical question:** What is the efficacy of the Ahmed FP7 glaucoma valve (AGV) implant compared to the Baerveldt 350 mm<sup>2</sup> glaucoma implant (BGI)?

**Study type:** Pooled analysis of two multicenter randomized clinical trials

**Number of patients:** 514

**Duration:** 5 years

**Eligibility:** Individuals 18 years and older with uncontrolled glaucoma defined as IOP greater than target despite maximum tolerated medical therapy, prior failed trabeculectomy or high-risk glaucoma, including neovascular and uveitic glaucoma

**Methods:** Patients were randomized to receive either an Ahmed FP7 or Baerveldt 350 mm<sup>2</sup> aqueous drainage device

**Results:** Cumulative failure at 5 years was lower in the BGI group (37%) than in the AGV group (49%) ( $P = 0.007$ ), with failure defined as IOP >18 mm Hg or reduced less than 20% from baseline, IOP <6 mm Hg, de novo glaucoma surgery, removal of the implant, loss of light perception vision, or severe vision loss

**Conclusions:** Baerveldt 350 mm<sup>2</sup> aqueous drainage device implantation had a higher cumulative success rate than the Ahmed FP7 drainage device, with a lower mean IOP, less glaucoma medication use, and lower rate of de novo glaucoma surgery. Rates of hypotony however were higher with BGI group (4.5%) as compared with the AGV group (0.4%).

**BOX 10.34.9 Effectiveness of Early Lens Extraction for the Treatment of Primary Angle-Closure Glaucoma (EAGLE) Study<sup>88</sup>**

**Clinical question:** Is early clear lens extraction more efficacious, safer, and cost-effective compared to LPI as first-line treatment for patients with newly diagnosed primary angle closure (PAC) with elevated IOP or primary angle-closure glaucoma (PACG)?

**Study type:** Multicenter randomized controlled clinical trial

**Number of patients:** 419

**Duration:** 3 years

**Eligibility:** Individuals aged 50 years or over, clear lens, and newly diagnosed PAC with IOP  $\geq 30$  mm Hg or PACG with IOP >21 mm Hg on at least one occasion.

**Methods:** Patients were randomized to treatment with either clear lens extraction or LPI and glaucoma drops (standard care).

**Results:** Mean IOP was lower (1.18 mm Hg), glaucoma medication use was lower (0.338 medications), and visual acuity was improved (three ETDRS letters) at 3 years in the clear lens extraction group as compared with standard care. European Quality of Life-5 Dimensions scores, NEI-VFQ-25, and Glaucoma Utility Index scores were significantly higher in the clear lens extraction group at 3 years. No serious adverse events occurred in either group and irreversible vision loss was noted in one patient in the clear lens extraction group and three patients in the standard care group. The incremental cost-effectiveness ratio for the clear lens extraction group versus standard care was £14,284 per QALY gained.

**Conclusions:** Early clear lens extraction resulted in greater clinical efficacy and was cost-effective compared with LPI as the initial treatment for patients with newly diagnosed PAC and elevated IOP or PACG.

IOP, Intraocular pressure; NEI-VFQ-25, National Eye Institute Visual Functioning Questionnaire 25; QALY, quality-adjusted life-year.

initial trabeculectomy. The CIGTS came on the heels of two RCTs in the United Kingdom comparing initial treatments for glaucoma: the Scottish Glaucoma Trial<sup>77</sup> and the Moorfields Primary Treatment Trial.<sup>78</sup> These studies suggested that initial trabeculectomy might be as good as any other initial treatment. The CIGTS, however, was more standardized, had a more heterogeneous patient population, and was of longer duration. Although visual function was the primary outcome, the designers of the CIGTS placed great emphasis on quality-of-life differences between the two groups. The investigators realized that even if the visual outcomes

were similar, one modality might result in better preservation of quality of life. Five-year results of the study, however, showed that to a first approximation, both groups did equally well on both the visual and quality-of-life outcomes.<sup>74,75</sup>

Although the use of MMC as an adjunct to glaucoma filtration surgery has become routine for many surgeons, the largest RCT in the area of antifibrosis agents remains the Fluorouracil Filtering Surgery Study (FFSS) (see Box 10.34.6).<sup>79</sup> The FFSS was the first multicenter clinical trial in glaucoma supported by the National Eye Institute, and it demonstrated the benefit of postoperative 5-FU injections in conjunction with trabeculectomy in eyes at high risk for failure. However, as with many reports of better efficacy of one treatment over another, one must not let the relative efficacy obscure the absolute efficacy. The 3- and 5-year success rates (defined as the “cumulative proportion of patients without reoperation or IOP failure”), 56% and 48%, respectively, for trabeculectomy with 5-FU in this group were disappointing.<sup>79</sup> Furthermore, the regimen of repeated 5-FU injections used in the study protocol is not used at all. This study did spark an interest, which continues to this day, in antifibrosis agents as adjuvants in filtration surgery.

Other important studies addressing antifibrosis agents in filtration surgery include, but are not limited to, studies by Skuta et al.<sup>80</sup> and Kitazawa et al.<sup>81</sup> Both groups performed small, RCTs comparing intraoperative MMC with postoperative 5-FU injections in eyes at high risk for filtration surgery failure and found that MMC lowered IOP more compared with 5-FU. These studies provided the rationale for MMC’s predominant role today as an adjunctive agent in glaucoma filtration surgery.

Two important RCTs have compared intraoperative 5-FU and MMC in “primary” trabeculectomies, that is, in eyes with no previous intraocular surgery. Both Singh et al.,<sup>82</sup> in a multicenter study, and Palanca-Capistrano et al.,<sup>83</sup> in a single-center study, randomized patients to either intraoperative MMC or 5-FU and concluded that both agents were equally effective.

The 5-year results of the Tube Versus Trabeculectomy (TVT) Study were published in 2012.<sup>84</sup> This multicenter RCT set out to determine whether tube shunt surgery or trabeculectomy is safer or more effective in eyes with prior ocular surgery. Patients were randomized to receive either a Baerveldt 350 mm<sup>2</sup> aqueous drainage device or a trabeculectomy with MMC 0.4 mg/mL for 4 minutes. With failure defined as IOP >21 mm Hg or not reduced by 20%, IOP <5 mm Hg, reoperation for glaucoma, or loss of light perception vision, the failure rate was lower in the tube group (30%) than in the trabeculectomy (47%) group ( $P = 0.002$ ) (see Box 10.34.7).<sup>84</sup> The results of a similarly designed multicenter RCT comparing tube versus trabeculectomy in eyes without previous surgery (The Primary Tube Versus Trabeculectomy Study) are expected to be available soon.

Another important set of multicenter RCTs were the Ahmed Baerveldt Comparison (ABC)<sup>85</sup> and Ahmed Versus Baerveldt (AVB)<sup>86</sup> studies, comparing the Ahmed FP7 glaucoma valve (AGV) implant to the Baerveldt 350 mm<sup>2</sup> glaucoma (BGI). A recent pooled analysis of the 5-year data from the ABC and AVB studies demonstrated lower cumulative failure in the BGI group (37%) compared with the AGV (49%) group ( $P = 0.007$ ), with failure defined as IOP >18 mm Hg or reduced by less than 20%, IOP <6 mm Hg, de novo glaucoma surgery, loss of LP or severe vision loss, or removal of the implant (see Box 10.34.8).<sup>85–87</sup>

The Effectiveness of Early Lens Extraction for the Treatment of Primary Angle-Closure Glaucoma (EAGLE) study was a large multicenter RCT comparing the efficacy, safety, and cost-effectiveness of clear lens extraction with those of LPI as first-line treatment in patients with newly diagnosed primary angle-closure glaucoma or primary angle closure with IOP of 30 mm Hg or greater.<sup>88</sup> The 3-year results of the study demonstrated that those randomized to early clear lens extraction had lower mean IOP, less glaucoma medication use, and higher quality of life scores compared with those receiving LPI as standard of care (see Box 10.34.9).<sup>88</sup> There were no significant differences in the rate of irreversible vision loss between the two groups. Economic evaluation of the EAGLE trial by Javanbakht et al.<sup>89</sup> suggested that early lens extraction is likely to be cost-effective over 3 years and may even become cost-saving by 10 years.

## BARRIERS TO THE PRACTICE OF EVIDENCE-BASED MEDICINE

The expanding volume of the medical literature is becoming increasingly difficult for clinicians to keep up with and apply to specific clinical situations. In a 1998 survey of general practitioners in the United Kingdom, most respondents cited lack of time as the primary barrier to practicing EBM.<sup>90</sup> Other barriers mentioned in the survey included lack of financial

gain in using EBM, lack of hard evidence, and patient expectations. A similar survey conducted in Denmark found that only 4.4% of responding hospital-based physicians could define and explain 12 commonly used EBM terms and that only 18% claimed to always practice EBM.<sup>91</sup> Many of the conclusions of these types of surveys are applicable to the ophthalmology community. Because no two patients are exactly alike, how can the practitioner be sure that the conclusions of an RCT are really applicable to the individual patient? Factors that must be considered include patient physiology, socioeconomic background, comorbidities, and risks of adverse outcomes.<sup>92</sup> As mentioned previously, because RCTs can take years to complete, the risk of their findings becoming obsolete may also deter clinicians from applying their conclusions.

How are clinicians really getting their evidence? The average practitioner will get the most exposure to evidence through secondary sources, which summarize the findings. These sources include journal editorials, the Cochrane Library, continuing medical education activities, in-clinic drug representative presentations, and “throwaway” journals. Faced with so many sources of information, clinicians seemingly are most likely to absorb the evidence that is presented in the clearest manner and is accompanied by straightforward clinical guidelines.

## FUTURE DIRECTIONS

The application of EBM to glaucoma may be improved in the future by better planning and organization of clinical trials combined with improved utilization of computers. Clinical trials in glaucoma have benefited from the organizational structure provided by such groups as the Ocular Hypertension Treatment Study Group. In the future, there may be further centralization of such groups into organizations that focus on broad glaucoma issues. The Pediatric Eye Disease Investigator Group (PEDIG) is one model of what such an organization might look like. PEDIG was created to coordinate pediatric clinical trials that feature streamlined protocols used by both academic and private practice clinicians.<sup>93</sup> The PEDIG coordinating center has made it less costly for the group to carry out multiple clinical trials in a timely and organized manner. Glaucoma research may someday benefit from similar efforts.

Neural networks make up a category of computer programs that hold promise as glaucoma clinical management tools. These networks are designed to be functionally similar to the human brain. One advantage that neural networks have over traditional programming methods is the potential to learn from prior examples. These networks also tend to use problem-solving approaches similar to those that humans use.<sup>94</sup> Lin et al.,<sup>95</sup> Bengtsson et al.,<sup>96</sup> Asaoka et al.,<sup>97</sup> and Andersson et al.,<sup>98</sup> among others, have separately had success with using neural networks to identify glaucomatous visual field defects and visual field progression. Neural networks are playing an increasing role in a broader category of computer-based tools for physicians, which are called *clinical decision support systems* (CDSSs).

The term *clinical decision support system* refers to software that is used to assist physicians with clinical decision making.<sup>99,100</sup> Glaucoma risk calculators are a type of CDSS that have been gaining increasing attention. Weinreb et al.<sup>101</sup> have discussed the potential value of a global risk calculator that would be based on variables, including age, IOP, cup-to-disc ratio, and central corneal thickness. A validated model estimating a patient’s 5-year risk for the development of POAG was subsequently developed<sup>59</sup> on the basis of the Ocular Hypertension Treatment Study and the European Glaucoma Prevention Study. This free online tool (<http://ohts.wustl.edu/risk>) calculates a patient’s 5-year risk of developing glaucoma, on the basis of the patient’s age, IOP, central corneal thickness, vertical cup-to-disc ratio, and pattern standard deviation. Glaucoma risk calculators are just one example of the many computer-based tools that may one day be available to clinicians to help with clinical decision making.

## CONCLUSIONS

Much lip service has been paid to EBM in the past few decades, but once one gets beyond the hype, the concept is valid and should be the fundamental underpinning of how we practice medicine. We should, to the best of our ability, perform tests, prescribe medications, and do procedures whose beneficial effects have been demonstrated in the literature. When information is lacking in the medical literature, the medical community should do its best, when feasible, to generate information to improve how we practice.

The last few decades have seen tremendous inroads into EBM for glaucoma treatment. In the mid-1980s, no large RCTs existed to guide practice, but today the results of several larger RCTs are available and their results

can be used daily in providing care to patients. The RCT has become our yardstick for making solid clinical decisions.

Barriers to the generation of good evidence-based information do exist. First, studies that address the important clinical questions have to be performed, and these studies must be designed and executed and their results analyzed correctly. Data from studies with negative results need to be captured, and new requirements for clinical trial registry may help in this regard. When there is more than one study on the same research question, appropriate meta-analyses need to be performed. Fortunately, such groups as the Cochrane Eye and Vision Group US are available to provide resources and expertise to guide the performance of this highly specialized task. Finally, dissemination and acceptance of findings remain daunting challenges in these times when “keeping up with the literature” is made difficult by increasing clinical volumes.

Fortunately, improvements in technology may help in the incorporation of evidence into practice. The Internet can make collaboration between multiple sites in a clinical trial easier. It has never been easier to access the medical literature, which is now, in larger part, available electronically. Computerized CDSSs may further improve the quality of clinical decisions and thus the care of patients.

# Anatomy and Physiology of the Extraocular Muscles and Surrounding Tissues

## 11.1

Joseph L. Demer

**Definition:** Muscles and associated tissues that provide eye movements and allow for binocular vision.

## Key Features

- Unique muscle type with specialized structure, metabolism, and innervation.
- Connective tissue gimbal supporting the eyeball and regulating its rotational properties.

## EMBRYOLOGY

The development of extraocular muscles, which are of mesodermal origin, begins at 3–4 weeks' gestation.<sup>1,2</sup> Early in gestation, neural crest cells divide and encircle the mesodermal cells destined to become primary myoblasts of individual extraocular muscles, guiding them to their appropriate positions and forming their connective tissue pulleys. Later, after the myoblasts develop through the primary and secondary stages, cranial nerves migrate to them from the brain and form neuromuscular junctions. The extraocular muscles and their surrounding tissues are present, and in their final anatomic positions by 6 months' gestation, but they mature later, even after birth.<sup>1</sup>

## GENERAL STRUCTURE OF EXTRAOCULAR MUSCLES

Extraocular muscles<sup>3,4</sup> and their terminal tendons<sup>5</sup> are composed of long, generally parallel fibers that transmit tension from end to end with little mechanical interaction between adjacent fibers. Each motor nerve axon in an extraocular muscle innervates only one or a few muscle fibers,<sup>1</sup> permitting extremely precise neural control of individual fibers according to their specific insertions on the sclera.

## GROSS ANATOMY OF THE EXTRAOCULAR MUSCLES

The orbits are oriented approximately 23° temporal to the midsagittal plane (Fig. 11.1.1).

### Origins of the Extraocular Muscles

All extraocular muscles except the inferior oblique originate at the orbital apex. The superior, inferior, medial, and lateral rectus muscles arise from a fibrous ring called the *annulus of Zinn*, and the optic nerve; the superior and inferior divisions of the oculomotor nerve; the abducens and nasociliary nerves; and the ophthalmic artery pass through it (Fig. 11.1.2). The superior oblique muscle arises from the orbital wall superonasal to the annulus of Zinn. The inferior oblique muscle originates from the maxillary bone in the orbital floor, adjacent to the lacrimal fossa, and posterior to the orbital rim.

**Fig. 11.1.1** The extrinsic muscles of the right eyeball in central gaze, seen from above.

### Compartments of the Extraocular Muscles

Each of the extraocular muscles contains multiple, specialized compartments that have independent functions. Each muscle has an orbital layer and a global layer.<sup>1</sup> The global layer is oculorotatory, passing through its pulley and ultimately inserting on the sclera. The orbital layer inserts on the inner surface of its connective tissue pulley, not on the globe, so that when the muscle contracts, the orbital layer retracts the pulley along the axis of the muscle, changing the muscle's functional origin and pulling direction.<sup>6–9</sup> The orbital layer of the superior oblique muscle is concentrically located on its exterior surface and is contiguous with a connective tissue sheath surrounding the superior oblique tendon, which, in turn, represents the extension of the centrally located global layer.<sup>10,11</sup> The inferior oblique muscle also has orbital and global layers, whose possible selective functions are unknown.<sup>12</sup> Electromyographic activity in the global layer differs from the orbital layer of rectus muscles,<sup>13</sup> but the sources of differential innervation remain unknown.

An additional, transverse compartmentalization occurs in the rectus and superior oblique muscles, subserving differential function across the widths of their broad tendinous insertions. The horizontal rectus muscles have superior and inferior transverse compartments, each innervated by a

**Fig. 11.1.2** The annulus of Zinn and surrounding structures.

separate motor nerve branch.<sup>14</sup> While one motor nerve branch innervates the entire inferior rectus muscle, a separate nerve coinnervates the lateral compartment.<sup>15</sup> The trochlear nerve divides in the orbit into medial and lateral divisions, each innervating a corresponding compartment of muscle fibers.<sup>11</sup>

## Insertions of the Extraocular Muscles

Rectus muscles transition to become tendons that insert anterior to the globe equator. The *medial rectus* inserts closest to the limbus, followed by the inferior, lateral, and superior rectus muscles in that order (MILS). The array created by connecting their insertions is called the *spiral of Tillaux* (Fig. 11.1.3).<sup>4</sup> The tendons are broad and composed of parallel fibers, so the fibers of each transverse muscle compartment insert in scleral positions corresponding to the compartment. For example, the medial rectus superior compartment acts on the superior part of the scleral insertion, whereas the inferior compartment acts about 5 mm inferiorly on the inferior part of the insertion.

The oblique muscles insert posterior to the globe equator (Fig. 11.1.4). The *superior oblique tendon* rolls into a cylindrical configuration to transit the trochlea within its sheath. Lateral to the trochlea, the sheath inserts into the nasal aspect of the superior rectus pulley, where the tendon fibers unroll into a broad, fan shape up to 18 mm wide; the lateral compartment fibers insert posterior to the equator and have a predominantly infraducting action, whereas the medial compartment fibers insert near the equator and have a predominantly incycloducting action. This distinction allows for surgical treatment of ocular torsion through manipulation of the anterior tendon fibers, such as by the Harada–Ito procedure.<sup>5</sup>

The orbital layer of the *inferior oblique muscle* inserts into the inferior rectus pulley, the inferior oblique sheath, and the inferior part of the lateral rectus pulley. The global layer inserts on the sclera in close proximity to both the macula and the inferotemporal vortex vein (see Fig. 11.1.4).

## Paths and Actions of the Extraocular Muscles

The paths of the extraocular muscles from their pulleys to their insertions determine their pulling directions; their posterior paths are relevant only to the magnitude of force generation. Through active adjustment of tensions in their orbital layers, the rectus pulley positions are maintained in positions as far posterior to globe center as their insertions are anterior to globe center. In secondary and tertiary gazes, this inflects muscle paths anterior to the pulleys so that pulling direction changes by one half of the change in eye position.<sup>9</sup> This feature of rectus muscles underlies Listing's law of ocular torsion and makes final eye position independent of the preceding sequence of horizontal and vertical rotations.<sup>8,16</sup>

**Fig. 11.1.3** Spiral of Tillaux. The structure of the rectus muscle insertions.

**Fig. 11.1.4** Posterior view of the eye with Tenon's capsule removed. (Adapted with permission from Parks MM. Extraocular muscles. In: Duane TD, editor. Clinical ophthalmology. Philadelphia, PA: Harper & Row; 1982. pp. 1–12.)

## MAJOR ACTIONS OF THE CYCLOVERTICAL EXTRAOCULAR MUSCLES

Muscle	Primary position	Adduction	Abduction
Superior rectus	supraduction incycloduction adduction	incycloduction adduction supraduction	supraduction
Inferior rectus	infraduction excycloduction adduction	excycloduction adduction infraduction	infraduction
Superior oblique	incycloduction infraduction abduction	infraduction abduction incycloduction	incycloduction abduction infraduction
Inferior oblique	excycloduction supraduction abduction	supraduction abduction excycloduction	excycloduction abduction supraduction

**Fig. 11.1.5** Major actions of the cyclovertical extraocular muscles.

The medial rectus muscle inserts on the nasal sclera. The lateral rectus muscle inserts on the temporal sclera. The superior rectus muscle inserts on the superior sclera (see Fig. 11.1.1) and has actions depicted in Fig. 11.1.5. The superior rectus muscle courses between the tendon of the superior oblique muscle and the levator palpebrae muscle. The inferior rectus muscle inserts on the anterior globe and has actions depicted in Fig. 11.1.5. The inferior rectus muscle courses between the globe and the inferior oblique muscle. Its pulley has fascial attachments to the lower lid retractors that may lead to widening or narrowing of the eyelid fissure during inferior rectus recession or resection, respectively.

The superior oblique muscle passes through the trochlea, a rigid pulley consisting of a cartilaginous saddle attached to periorbita of the frontal bone in the superior nasal orbit. In central gaze, the superior oblique tendon forms an angle of 51° with the visual direction and has actions shown in Fig. 11.1.5. Contraction of the superior oblique orbital layer shifts the superior rectus pulley nasally during vestibulo-ocular reflexes, such as ocular counterrolling.<sup>17</sup>

The inferior oblique muscle travels through its pulley that is inferior to and partially coupled to the inferior rectus pulley<sup>18</sup> and has actions shown in Fig. 11.1.5. The inferior oblique pulley is retracted posteriorly when the orbital layer of the inferior rectus muscle contracts in infraduction but shifts anteriorly when the inferior rectus relaxes.<sup>18</sup> Shift in the inferior oblique pulley position causes its pulling direction to change by one-half of eye position, consistent with Listing's law, but contraction of the inferior oblique orbital layer shifts the inferior rectus pulley nasally and lateral rectus pulley inferiorly during vestibulo-ocular reflexes, such as ocular counter-rolling.<sup>17</sup>

## Innervation

The *oculomotor (third cranial)* nucleus is located in the midbrain. Its nerve travels through the cavernous sinus and superior orbital fissure, where it

divides into superior and inferior divisions. The superior division supplies the levator palpebrae superioris and superior rectus muscles. The inferior division supplies the medial rectus, the inferior rectus, the inferior oblique, and the ciliary ganglion. The *trochlear (fourth cranial)* nucleus originates in the midbrain and innervates the contralateral superior oblique muscle. The *abducens (sixth cranial nerve)* nucleus originates in the dorsomedial pons and innervates the ipsilateral lateral rectus muscle.

Rectus muscles are innervated from the global surface at approximately the junction of the middle and posterior third of each muscle. The inferior oblique muscle receives its innervation at the lateral border of the inferior rectus pulley.<sup>18</sup> The superior oblique muscle is innervated from its superolateral surface in the deep orbit.<sup>9</sup> Separate compartmental branches of each motor nerve divide from the main trunk posterior to the entry point in each extraocular muscle and further arborize on the global surface before traveling anteriorly to selectively enter each compartment of muscle fibers.<sup>15</sup>

## Blood Supply

The *ophthalmic artery*, a branch of the *internal carotid artery*, supplies the extraocular muscles. The lateral rectus muscle is supplied by the *lacrimal artery*, a branch of the *ophthalmic artery*. The inferior rectus muscle and inferior oblique muscles are supplied by the *infraorbital artery*, a branch of the *internal maxillary artery*, arising from the *external carotid artery*. The *anterior ciliary arteries* that supply the anterior segment of the eye travel within the rectus muscles and enter the sclera just anterior to the rectus insertions, anastomosing with conjunctival vessels at the limbus and joining the *major arterial circle of the iris*. The oblique muscles do not convey circulation to the anterior segment.

Surgical disinsertion of rectus muscles permanently interrupts the anterior ciliary arteries. If surgery is performed on multiple rectus muscles simultaneously, anterior segment ischemia may result, as discussed

**Fig. 11.1.6** The orbital pulley system. (Adapted from Demer J. Current concepts of mechanical and neural factors in ocular motility. *Curr Opin Neurol* 2006;19:4–13.)

further in Chapter 11.13.<sup>19</sup> The superior and inferior orbital veins drain the extraocular muscles.

## THE ORBITAL INFRASTRUCTURE AND ANATOMY

*Tenon's capsule* is a fibroelastic membrane that begins 1 mm from the limbus, where it is fused with the conjunctiva; it then caps the globe posteriorly to the optic nerve.<sup>14</sup> Its inner surface is smooth, which allows free gliding of the adjacent structures within it. Its equatorial region is penetrated by the extraocular muscles at their pulleys.<sup>6</sup>

Tenon's capsule thickens at and posterior to the equatorial region, where it forms a socket and is penetrated by the extraocular muscles.<sup>6</sup> At the site of penetration, a sleeve is formed around the penetrating extraocular muscle with increasing cross-linked collagen and elastin. This sleeve has significant fibroelastic attachments to the periorbita and adjacent sleeves (Fig. 11.1.6). These sleeves create compliant pulleys that redirect the extraocular muscles and act as functional origins.<sup>6,8,20</sup> The pulleys are posterior to the equator of the globe with total anteroposterior extents of 13–19 mm, although it is likely that only the middle 5–8 mm of this extent is mechanically stiff.<sup>6</sup> The pulley sleeves contain collagen, elastin, and innervated smooth muscle. The sleeves extend both anteriorly and posteriorly from the site of maximal pulley effect to form slings that stabilize the extraocular muscle paths through fibroelastic attachments to periorbita and surrounding slings (see Fig. 11.1.6).

The inferior part of the pulley system is a connective tissue sling, called the *suspensory ligament of Lockwood*,<sup>21</sup> and contains the inferior oblique pulley.<sup>18</sup> Tenon's capsule thins posteriorly, allowing free movement of the

penetrating optic nerve and vessels with globe movement. Each muscle is surrounded by a thin, fibrous muscle capsule throughout its extent.

## CLINICAL CORRELATES

Magnetic resonance imaging (MRI) has shown that pulley issues are important in strabismus.<sup>8,22,23</sup> Congenital rectus pulley malposition may produce “A” patterns (superior location of lateral rectus pulley relative to medial rectus pulley), “V” patterns (inferior location of lateral rectus pulley relative to medial rectus pulley), and incomitant hypertropia.<sup>22,24</sup> Pulley instability (e.g., produced by surgical damage or connective tissue disease) may result in an incomitant strabismus.<sup>25</sup> Pulley damage resulting in failure of pulley retraction during muscle contraction produces incomitant strabismus by restricting posterior movement of the muscle insertion.<sup>25</sup> Posterior fixation (in German *faden*, meaning “thread”) surgery works by limiting posterior pulley excursion.<sup>26</sup> The muscle pulleys redirect the rectus muscles and limit the effect of transposition surgery,<sup>27–29</sup> lessening the effective change in pulling direction that would occur if such structures were not present. Severing of the intermuscular septal connections is not necessary for rectus recession.<sup>30</sup> Posterior dissection may result in pulley damage.

## EXTRAOCULAR MUSCLE PHYSIOLOGY

Extraocular muscles are unique because of their highly specialized combination of muscle cells, which have unique structural and metabolic properties.<sup>1</sup> The oculorotatory global layer is dominated by fast twitch-generating singly innervated fibers (SIFs) with exceedingly fine motor unit size (one axon per muscle fiber). This allows for large, rapid, precise movements.

**BOX 11.1.1 Agonist–Antagonist Pairs (in the Same Eye)**

Medial rectus–lateral rectus  
 Superior rectus–inferior rectus  
 Superior oblique–inferior oblique

Orbital layer SIFs are specialized for intense oxidative metabolism, have a larger blood supply, and are fatigue resistant, allowing for more sustained pulley tension. Extraocular muscles are luxuriantly perfused, with even greater vascularity in the orbital than global layers.<sup>31</sup>

**Hering's and Sherrington's Laws**

Rotation of one eye is termed *duction*. During duction, contraction of one extraocular muscle normally results in simultaneous relaxation of its antagonist in the same eye. Agonist–antagonist pairs are listed in [Box 11.1.1](#). This relationship between agonist–antagonist pairs in one eye is termed Sherrington's law of reciprocal innervation. In Duane's retraction syndrome, Sherrington's law is violated because of cocontraction of the medial rectus and lateral rectus muscles during adduction.<sup>32</sup>

Rotation of both eyes in the same direction is termed *version*. During version, the muscles of both eyes make an equal effort to rotate them to the same gaze angles (Hering's law).<sup>33</sup> These paired agonists are called yoke muscles ([Box 11.1.2](#)). Hering's law explains the findings of primary and secondary deviations in paralytic strabismus. Innervation to the yoke muscles is always determined by the fixing eye. When the normal eye fixates, the resultant strabismus is termed *primary deviation*. When the paretic eye fixates, the resultant strabismus is larger and termed *secondary deviation*. Note that a version is composed of duction in each eye, so Sherrington's law also applies. Dissociated vertical and horizontal deviations violate Hering's law. Vergences are rotations of the two eyes in opposite directions and may be physiological as in the case of convergence to view

**BOX 11.1.2 Paired Agonists (in Opposite Eyes)**

Left medial rectus–right lateral rectus  
 Left lateral rectus–right medial rectus

# Evaluating Vision in Preverbal and Preliterate Infants and Children

## 11.2

Kyle E. Miller, David B. Granet, Gary R. Diamond<sup>†</sup>

**Definition:** Visual acuity in preverbal infants is defined as a motor or sensory response to a threshold stimulus of known size at a known testing distance. Visual acuity in preliterate but verbal children is described as the smallest target of known size at a known testing distance correctly verbally identified by a child.

### Key Features

- In preverbal children, visual acuity may be quantified by a motor response (optokinetic nystagmus testing, forced choice preferential looking) as well as by a sensory response (visual evoked responses).
- In preliterate but verbal children, visual acuity may be quantified by verbal or motor identification of graded non-Snellen optotypes (Landolt rings, HOTV test, tumbling E test).

### INTRODUCTION

Vision screening begins in infancy and progresses to figure or letter (optotype) acuity testing by age 4 years. The American Academy of Pediatrics, the American Academy of Ophthalmology, and the American Association for Pediatric Ophthalmology & Strabismus have put forth a consensus statement regarding the evaluation of vision in children. This statement recommends attempting optotype acuity testing (standardized figures or letters) in cooperative 3-year-olds, and then repeating yearly.<sup>1</sup> Specialized techniques for visual acuity quantification are necessary when evaluating children younger than 3–4 years of age. These techniques include observation, fixation targets, optokinetic nystagmus, visual evoked potentials, forced-choice preferential looking, specially constructed graded optotypes, and digital photoscreeners.

### HISTORICAL AND OBSERVATIONAL TECHNIQUES

Much can be learned from the historical descriptions of a child's visual behavior from family members. Parents or caregivers are asked routinely whether the child responds to a silent smile, enjoys silent mobiles, and follows objects around the environment. Pertinent observations include strabismus, nystagmus, persistent staring, and inattention to objects. A younger sibling's visual behavior may be compared with that of an older child.

The pupillary light response is not equivalent to visual ability, but its presence indicates intact afferent visual neurological pathways to the level of the brachium of the superior colliculus and efferent pathways to the iris sphincter. This reflex is present in premature babies with gestational age between 30 and 32 weeks.<sup>2</sup> Visualization in very young children sometimes requires a magnifying glass, as their pupils are smaller than those of older children (decreased sympathetic tone), and the light responses are of small amplitude. Dilatation to direct illumination (paradoxical pupillary response) has been described in Leber's congenital amaurosis, optic nerve hypoplasia, congenital achromatopsia, and congenital stationary night blindness.<sup>3</sup> Nystagmus, a sign of binocular visual impairment, is absent

in cortical blindness<sup>4</sup> and often is not found in association with unilateral visual defects.

The blink to a bright light is a response noted by 30 weeks of gestational age and occasionally is present in decorticate infants. The blink to a threatening gesture is another reflex, usually present by 5 months; however, care must be taken to not push air against the child's corneas and elicit a blink by that mechanism.

### FIXATION TARGETS

Visual fixational abilities may be demonstrated in full-term newborns by using a high-contrast target. A flashlight is a poor target because it has no edges; stripes, dots, or checkerboards are preferred. Full-term infants younger than 3 months of age "follow" a small target by using hypometric saccades<sup>5</sup>; these infants may generate smooth pursuit movements to a large target, such as an optokinetic drum. Vertical saccades become identifiable by about 2 months of age, and prior to that horizontal saccades can be seen. Because saccadic palsies are common in young children who have central nervous system damage, spinning an upright child demonstrates the presence of saccades as the rapid recovery phase of the spin-induced nystagmus. If no rapid phase can be stimulated, the child's vision cannot be evaluated by his or her ability to "follow" a small target, as neither a saccadic nor a smooth pursuit system is yet available. In addition, a child who has normal fixational behavior should dampen spin-induced nystagmus in 3–5 seconds; a blind or poorly sighted child cannot use fixational dampening and beats for 15–30 seconds until mechanical dampening occurs.

In slightly older children, small, colorful, familiar toys generate the best, albeit often momentary, interest. Two methods of evaluating visual acuity using toys is with "Fix & Follow" (F&F) or "Central, Steady, & Maintained" (CSM) testing. For F&F testing, a small toy or fixation target is moved slowly in front of the child to observe the child's fixation and motility. Asymmetry in monocular testing can give an indication of amblyopia. CSM notation provides information regarding potential eccentric fixation (central), ocular motility or nystagmus (steady), and ability to keep fixation (maintained).

### OPTOKINETIC NYSTAGMUS

Evaluation of optokinetic nystagmus was the first "technological" approach to acuity measurement in preverbal children; square-wave gratings (alternating black and white stripes with sharp, distinct interfaces) placed on arcs were moved across an infant's visual field.<sup>6</sup> Standardized drums that contain stripes that subtend small fractions of the infant's visual field are available (Fig. 11.2.1) but often do not hold interest, are spun at varying and uncalibrated rates, and are bathed in variable illumination. When determination is performed binocularly, full-term infants have approximately 20/400 (6/120) acuity at birth. This method measures acuity by means of an ocular motor response technique, but using this can result in underestimation of the acuity in some children who have disturbed oculomotor systems. The horizontal saccadic system is present at term birth, whereas the vertical saccadic system does not develop until 4–6 weeks later.

### VISUAL EVOKED POTENTIALS

On the basis of the observation that visual stimuli yield a measurable electroencephalographic pattern received by occipital scalp electrodes, various methods, which include the use of bright-flash stimuli, square-wave gratings, and phase-alternating checkerboards, have been employed to evaluate

<sup>†</sup>Deceased

**Fig. 11.2.1 Optokinetic Drum Testing.** The movements of the patient's eyes are examined while they fixate on the moving stripes of the drum.

**Fig. 11.2.2 Evoked Potential Test.** The occipital electrodes are placed in position.

**Fig. 11.2.3 Checkerboard pattern for evoked potential test.**

acuity. Only the last two targets can be calibrated. Many investigators using visual evoked potentials have found 20/200 (6/60) acuity in full-term newborns.<sup>7</sup> Acuity of 20/20 (6/6) may be demonstrated by 6–12 months, considerably before the age indicated by optokinetic nystagmus testing, perhaps reflecting that this electrophysiological test evaluates acuity by direct recording of sensory afferents, the only test to do so.

Visual evoked potential testing (Figs. 11.2.2 through 11.2.4) can be used to evaluate acuity in children with aphakia,<sup>8</sup> amblyopia,<sup>9</sup> or strabismus and in those who have large refractive errors. Although the test directly evaluates vision by means of a sensory process, a waveform of normal appearance has been recorded in the occasional decorticate infant who later behaves as if blind, which implies a subcortical contribution; the

#### WAVEFORM OF TYPICAL VISUAL EVOKED POTENTIAL

**Fig. 11.2.4 Waveform of Typical Visual Evoked Potential.** The amplitude of the major positive wave and elapsed time from stimulus onset to this wave are the most important features of the visual evoked potential. (From Thurtell MJ, et al. Evaluation of optic neuropathy in multiple sclerosis using low-contrast visual evoked potentials. *Neurology* 2009;73(2):1849–57.)

**Fig. 11.2.5 Teller acuity cards.** (Copyright© 2012 American Foundation for the Blind. All rights reserved.)

exact origin of the response remains unknown.<sup>10</sup> As the response waveform changes markedly between 1 and 6 months, care must be taken to compare waveforms with those of age-matched controls.

#### FORCED-CHOICE PREFERENTIAL LOOKING

This behavioral technique is based on the observation that infants prefer to view a pattern stimulus rather than a homogeneous field.<sup>11</sup> Using flat, calibrated, square-wave gratings, this tendency may be observed by a trained individual.<sup>12</sup> As with the optokinetic nystagmus test results, a full-term newborn differentially responds to 20/400 (6/120) gratings; the response to 20/20 (6/6) gratings occurs at 18–24 months.<sup>13,14</sup> A smaller and simpler apparatus, with the target presenter unmasked, has been devised; this is more suitable for clinical applications (Fig. 11.2.5).<sup>15</sup> Further, use in the clinical examination office has been validated with the simple use of free cards.

The child must be alert and able to generate neck and eye movements, which disqualifies many whose hypotonia and inattention prevent such

**Fig. 11.2.6** HOTV test. (From Hartmann EE, et al. Preschool vision screening: Summary of a task force report. *Pediatrics* 2000;106(5):1105–6.)

purposeful movement—a significant limitation in the evaluation of developmentally delayed infants. Thus, as with the optokinetic nystagmus technique, vision is evaluated by means of a motor response. In addition, this test presents a resolution acuity task, not a recognition acuity task, and thus may be less ideal for the detection of amblyopia than the visual evoked response test.<sup>16,17</sup> However, the testing cards are simple, are portable, and cannot lose calibration. Evidence exists of experiential effects, and because the cards can be presented with the stripes in one orientation (vertical) only, the acuities of some children with optically uncorrected astigmatism may be estimated erroneously when using this technique.<sup>18</sup> Children who have nystagmus may be more difficult to test, but shifting the cards 90° to the direction of the nystagmus can help. Additionally, those who have visual field defects may have difficulty finding the targets.

## GRADED OPTOTYPES

Rarely, children as young as 18 months can respond to Snellen optotypes, but it is uncommon for children younger than 4.5 years to read a standardized Snellen acuity chart reliably—despite their parents' confidence. Tests useful in the age range 2–5 years include Allen pictures, Lea symbols, Landolt ring test, the HOTV test, and the tumbling E test.<sup>2</sup>

Allen pictures and Lea symbols allow for testing acuity by using familiar pictures. Allen pictures include horse, cake, car, and bird, among others, and there are four Lea symbols: circle, square, house, and apple. Both have good correlation with Snellen acuity and can be performed using a matching card thereby decreasing the age at which children successfully complete the testing.

The HOTV test requires pattern recognition and matching of progressively smaller optotypes with those on a handheld card. These letters are chosen to be of average recognition difficulty and have a vertical axis of symmetry, which obviates right–left confusion common in this age group. An advantage is the exact correspondence of the target to the graded Snellen optotypes (Fig. 11.2.6).

Landolt rings are discontinuous circles; the child points to a similar ring on a handheld card. The test often confuses the younger child and perhaps is more useful for use in illiterate adults; however, its direct correspondence to Snellen is an advantage. The tumbling E test requires matching orientation of the letter “E” with a figure or the child's fingers; unfortunately, right–left disorientation is common in this age group, limiting the usefulness of this test. Its major advantage is the direct correspondence to graded Snellen optotypes.

**TABLE 11.2.1** Visual Acuity of Infant Eyes

Test	2 Months	4 Months	6 Months	1 Year	Attainment (months)
Opticokinetic nystagmus test	20/400	20/400	20/200	20/80	24–30
Forced choice preferential looking test	20/400	20/200	20/200	20/50	18–24
Visual evoked response test	20/200	20/80	20/60–20/20	20/40–20/20	6–12

## Digital Photoscreening

The use of a photoscreening device was first introduced in the 1970s; however, the introduction of digital technology has increased its use. The first digital photoscreener with on-site result interpretation was introduced in the late 1980s by a team led by David Granet at the University of California San Diego. Several versions now exist, with the most common one using infrared photography to obtain an image of each eye, and the image is analyzed for amblyogenic risk factors. These devices allow for screening of children as young as 6 months of age and are recommended to be used at the 12-month, well-child visit and annually thereafter until acuity can be tested directly.<sup>1</sup>

## MATURATION OF VISUAL ACUITY

Although the central cones function by full-term birth, acuity as measured by the preceding techniques does not approach 20/20 (6/6) until 6–30 months, depending on the examination technique (Table 11.2.1). Reasons for this delay include the incomplete development and specialization of photoreceptors, maturation of synapses in the inner retinal layers, myelination of the upper visual pathways, and maturation of the ciliary body. Foveal cones do not attain adult appearance until 4 months after full-term birth,<sup>19</sup> and true visual pathway myelination continues until 2 years of age.<sup>20</sup> Interestingly, ambient illumination increases the rate of visual system myelination.<sup>21</sup>

Occasionally, infants fail to develop visual fixational abilities until they are 6–12 months of age, but at a later age, they develop normal visual behavior, termed *delayed visual maturation* (DVM). These children, often small for gestational age or developmentally delayed, have a normal or sluggish pupillary response, no nystagmus, and normal globe structure and present challenges to the clinician. The electroretinography result is normal; the visual evoked response has been reported variously as normal,<sup>22</sup> reduced in amplitude, or absent.<sup>21</sup> These children are postulated to have a cortical synaptic developmental delay. No clear explanation exists for children who have normal visual evoked response test results but present with visual inattention and other aspects of this syndrome. The parents are reassured and the child is examined frequently during this period until visual attention reaches the expected level.

[ExpertConsult.com](http://ExpertConsult.com)

## Definitions:

- *Phoria*: a latent visual axis deviation held in check by fusion.
- *Tropia*: a manifest visual axis deviation (also known as *strabismus* or *squint*).
- *Intermittent tropia*: an intermittent visual axis deviation that may exist only in certain gaze positions and target distances or when the fusion is altered (when person is ill, tired, etc.).
- *Ductions*: monocular movements into various gaze positions; each eye views in the same direction.
- *Versions*: synchronous simultaneous movements of the two eyes in the same direction.
- *Vergences*: binocular eye movements into opposite gaze directions.
- *Primary position*: position of the eyes when looking straight ahead with body and head erect.

## Key Features

- Alignment of the visual axes can be evaluated by objective and subjective clinical methods.
- Evaluation of eye movements can be accomplished by objective and subjective techniques.
- Patients who have mechanical limitations of eye movements can be evaluated, if the patient is cooperative, in an outpatient setting by using forced-duction testing and active force-generation testing.

## EVALUATION OF OCULAR ALIGNMENT

### Introduction

The clinician evaluating ocular alignment must first decide what information is required—the eye alignment during everyday binocular viewing, or the maximal deviation of the visual axes under conditions of disrupted binocular vision, or both. Subjective methods are useful in cooperative, communicative older patients, but objective methods must be used in younger patients or those less cooperative. Finally, some testing methods are useful only under research laboratory conditions.

### Laboratory Methods

Most laboratory tests are objective. The absolute position of the eye in space may be determined by measurement of the quantity of light reflected by the sclera of a deviated eye. The electro-oculogram (EOG) is generated by alterations in direct current between the front and back of the eye as the eye rotates; this voltage change is detected by suitably placed electrodes. Finally, insulated wire placed in a silicone rubber limbal annulus (eye coil) generates a current in response to a magnetic field; this very precise technique is limited by irritation caused by the device but may be used to detect horizontal, vertical, and torsional changes in eye position.

### Clinical Methods

The examination of the patient starts as soon as the patient enters the clinic. The way the patient moves, interacts, and navigates around the room and the presence or absence of anomalous head positioning should be evaluated, especially when the patient is comfortable in his or her own setting. In the examination room, the patient may be stressed enough to hide such problems as intermittent strabismus and phorias. Ideally, the clinician should accompany the patient from the waiting room to the examination chair and carefully note the position of the patient's head when it is mobilized in free space. Anomalous head positions may indicate restrictive or paralytic strabismus, the presence of a null point in a patient who has nystagmus, or alphabet-pattern strabismus. But it also can be present in other conditions, such as refractive errors, neck musculoskeletal system anomalies, and so on. Usually, a patient places the head in a position that provides comfortable single binocular vision for the straightened view, but occasionally the head is placed to separate diplopic images maximally or to suppress the less desired second image. The examiner must distinguish head turns, tilts, and vertical head positions and attempt to quantitate these to within 5°.

Once the patient is seated in the examination chair, the patient's lid position is noted; lid asymmetry is usually present in patients who have vertical strabismus. In cases of hypotropia, there is often associated pseudoptosis of the eyelid because of the downward rotation of the eye. Once the eye is straightened, the lid is no longer ptotic. Other soft tissue and bone structures that surround the eye may give false impressions about ocular alignment to the patient's family and the examiner. Epicanthal skin folds that extend over the nasal sclera in a small child may simulate esotropia; this is noted by parents, particularly in pictures and/or when the child looks with a head turn. Unilateral or asymmetrical lower lid retraction may give the impression that one eye is higher than the fellow eye. Vertical displacement of an orbit may simulate vertical strabismus, and hypertelorism may simulate exotropia. The examiner can diagnose strabismus only after the appropriate alignment testing has been performed.

The optic axis can be determined accurately only with alignment of the Purkinje images with a coaxial light through a telescope; this light intersects the retina between the disc and the fovea.<sup>1</sup> For clinical purposes, the optical axis may be assumed to strike the fovea. An observer considers the eye as viewing along its *pupillary axis*, a line through the pupillary center perpendicular to the cornea. The visual axis outside the eye is usually nasal to the pupillary axis ("positive angle Kappa ( $\kappa$ )") at an average angle of 5° in emmetropic eyes, 7.5° in hyperopic eyes, and 2° in myopic eyes (Fig. 11.3.1).<sup>2</sup> In some myopic eyes, the visual axis is temporal to the pupillary axis, which gives a "negative angle  $\kappa$ ." In some children who have cicatricial retinopathy of prematurity, the fovea is dragged temporally, which results in large positive angle  $\kappa$  and pseudo-exotropia.

### Objective Clinical Methods

Objective clinical methods to determine and measure deviations of the visual axes include corneal light reflex tests, cover tests, and haploscopic tests (i.e., synoptophore, etc.). These tests do not require any response by the patient and thus are independent of the patient's ability to interpret the testing environment.

<sup>†</sup>Deceased

**Fig. 11.3.1 The Angle  $\kappa$ .** This is the displacement in degrees of the pupillary axis from the optical axis. The positive angle  $\kappa$  provides the illusion of exotropia in this left eye.

**Fig. 11.3.2 Hirschberg Light Reflex Method.** The patient has a left esotropia. Note the corneal light reflex at the temporal pupillary border of the left eye while the reflex is centered in the pupil of the right eye.

### Corneal Light Reflex Tests

Corneal light reflex tests, the oldest testing methods, are suitable for all patients. They do not take into account the angle  $\kappa$  and do not require both eyes to discern a fixation target or to be able to move into a given position to take up fixation of the target. The Hirschberg method relies on a pupil size of 4 mm and assumes each millimeter of light displacement across the cornea is equivalent to  $7^\circ$  of decentration or  $15\Delta$ . A light reflection signifies a  $15^\circ$  or  $30\Delta$  deviation at the pupillary border (Fig. 11.3.2), a deviation of  $30^\circ$  or  $60\Delta$  at the midiris, and a deviation of  $45^\circ$  or  $90\Delta$  at the limbus. Studies indicate that 1 mm of light displacement is equal to  $18^\circ$  of strabismus, and  $21^\circ$  if referred to the frontal plane by photographic techniques.<sup>3</sup> The test should be performed with the light centered in each eye's pupil to detect the presence of secondary deviations (see later). The disadvantages of this test are the estimations necessary to measure the eye deviation and the inability to control accommodation when testing at near fixation because the measuring light serves as the fixation target. Distance testing is difficult because of the dimness of the target light reflected in the corneas. The test again requires pupils to be 4 mm, and will give wrong estimations if the pupil size is drastically different from 4 mm.

The Krimsky test quantifies the light reflex displacement using appropriately held prisms. The original description suggested placing the prism before the aligned eye (Fig. 11.3.3), but most users today find it easier to hold the prism before the deviating eye.<sup>4</sup> The results are identical unless a secondary deviation (measurement taken with the paretic or mechanically restricted eye fixing) exists. An arc perimeter may be used to measure larger deviations by alignment of a light in the deviated eye, with the deviation read in degrees from the arc perimeter scale. The Maddox tangent scale at 3.3 ft (1 m) or 16.5 ft (5 m) testing distance may be used in a manner similar to that with the arc perimeter. Using the major amblyoscope, a light may be projected on each cornea and the tubes moved to center the light reflexes.

**Fig. 11.3.3 Krimsky Light Reflex Method (Same Patient as in Fig. 11.3.2).** The strength of a base-out prism over the fixing right eye sufficient to center the pupillary light reflex in the esotropic left eye is defined as the amount of left esotropia.

**Fig. 11.3.4 Prism Diopters.** Geometric definition of the prism diopter, a tangent function. The relationship between prism diopters per degree and degrees of strabismus is nonlinear ( $90^\circ$  represents an infinite number of prism diopters).

Prisms must be appropriately handled to yield accurate measurement of strabismus (Video 11.3.1).<sup>5</sup> They deflect light toward the base, but the patient views the light as deflected toward the prism apex. The prism diopter is defined as the strength of prism necessary to deflect a light beam 0.4 inches (1 cm) at 3.3 ft (1 m) distance (Fig. 11.3.4). As a tangent function, the prism diopter is not linear and increases in size as the deviation increases, but for small deviations  $1^\circ$  approximates  $1.7\Delta$ . Glass prisms are manufactured rarely today but are calibrated to be held in the Prentice position with the back-surface perpendicular to the visual axes. Plastic prisms, whether loose or in bar form, must be held with the rear surface in the frontal plane to approximate closely the position of minimal deviation of light through the prism. Prisms cannot be stacked base to base, as the sum prism strength is much greater than the sum of the individual prism strengths, but they may be stacked with bases  $90^\circ$  apart. Large deviations are best neutralized with the prisms divided between the two eyes. For measurements when patients view in eccentric gaze positions and in those undergoing the head tilt test, care is required to ensure that the prisms are held in the frontal plane.

### Cover Tests

These objective tests detect and measure horizontal and vertical strabismus, but they cannot measure torsional deviations and detect only some and not all torsional deviations. All cover tests demand the ability of each eye to discern the fixation target and to move to take up fixation upon that target.

The cover test detects tropias—constant visual axis deviations. The examiner observes the uncovered eye for movement as its fellow is

See clip:  
11.3.2  
to  
11.3.5

covered with a paddle, thumb, or remote occluder (Video 11.3.2). Nasal movement implies exotropia (Video 11.3.3), temporal movement esotropia (Video 11.3.4), upward movement hypotropia, and downward movement hypertropia (Video 11.3.5) of the uncovered eye.<sup>6</sup> Each eye is covered in turn. An accommodation-controlling fixation target of about 20/40 (6/12) size is presented to the patient, who ideally describes the target (Video 11.3.1). Small toys are suitable to be used in young children, but bright white lights are avoided because these patients cannot accommodate on the contours of a light. Tropias established by the cover test may be measured by using the simultaneous prism and cover test; a prism of appropriate strength held in the appropriate direction is introduced before one eye as its fellow is covered. Prism strength is increased until eye movement ceases; this prism strength corresponds to the size of the strabismus (Videos 11.3.6 and 11.3.7). The test is then repeated with the prism before the other eye.

See clip:  
11.3.6  
and  
11.3.7

The uncover test requires observation of the covered eye as the cover is removed (Video 11.3.2). If that eye is deviated under cover, it may regain fixation or may remain deviated. The former implies the presence of *phoria*, a latent deviation held in check by sensory fusion, or *intermittent tropia* (Video 11.3.8); the latter implies tropia with fixation preference for the fellow eye (Video 11.3.2).

See clip:  
11.3.2  
and  
11.3.8

Phorias may be detected more directly by using the alternate cover test, in which each eye is occluded alternately to dissociate the visual axes maximally. Care must be taken to permit time for each eye to reside behind the cover (the cover must not be “fanned” before the eyes) (Video 11.3.9). Appropriately held prisms enable quantitation of the phoria or the tropia (Video 11.3.6). Some patients have poorly defined endpoints and a range over which eye movements shift from one direction to the opposite as prism strength is increased; the strabismus measurement may be estimated as the midpoint between clearly defined movements in each direction. For most clinical purposes, measurements within 2 D are sufficiently accurate. Cover test measurements are influenced by the presence of eccentric fixation; its presence must be investigated in patients who have severe amblyopia.

See clip:  
11.3.6  
and  
11.3.9

The eye behind the prism should be the “fixing” eye. If the cause of strabismus is paralytic or restrictive, patients may have greater cover test measurements when the paretic or restricted eye fixes in a given gaze position (secondary deviation) than when the sound eye fixes (primary deviation). This phenomenon arises from Hering’s law, which demands equal innervation to yoke muscles; thus, the yoke of a paralyzed or restricted muscle receives excess innervation when the pathological eye is fixing.

Strabismus should be detected and measured in primary position at distance and near fixation and in gaze up, down, right, and left 30° from primary position. The nine “diagnostic gaze positions” include the above plus up and right, up and left, down and right, and down and left; these are useful to measure cyclovertical muscle palsies. For patients who have oblique muscle dysfunction, measurements are taken with the head tilted 30° right and left at distance fixation.

### Subjective Clinical Methods

Subjective clinical methods include diplopia tests and haploscopic tests, which require patient cooperation, intelligence, and ability to communicate the sensory perception to the examiner.

The red glass test requires the patient to alert the examiner when the red light viewed behind a red filter before the right eye and a white light viewed with the left eye are superimposed or displaced one from the other. Fusion is disrupted by the red glass, and thus, horizontal and vertical phorias are uncovered and measured; torsional deviations are not detected by this method. The gaze position of maximal image separation is a clue to the identity of paretic or restricted muscles. This is a useful bedside test, but accommodation is not controlled.

The Maddox rod consists of closely aligned, powerful glass or plastic cylinders. When illuminated, these cylinders project a line on the patient’s retina perpendicular to the groove orientation. The line is aligned horizontally to detect and measure horizontal phorias (accommodation cannot be controlled with this test). Torsional diplopia also may be detected and quantified using the “double Maddox test”; the Maddox rod is placed in a trial frame scaled in degrees. It is common to place two Maddox rods of different colors (red and white) in each trial frame cell and permit the patient to rotate each to his or her perception by using the trial frame dial. An easy method is to align the grooves at 90° on the trial frame, shine the light into one eye at a time, covering the fellow eye to orient the patient to the individual red and white lines. Then distort either one of the rods to be off by about 25° by turning the knob of the trial frame to make the angle difference between the lines obvious. Then, the patient is asked to

turn either rod by using the dialing knob to make them “parallel” again. The torsional position of each eye may be read directly in degrees from the angular scale used for cylinder axes. This test should be repeated three times to check the patient’s consistency.

Haploscopic devices, such as the major amblyoscope, present each eye with a significantly different target from its fellow eye. These devices measure horizontal, vertical, and torsional deviations by alternately illuminating the fixation targets presented to each eye; the tubes are positioned appropriately until no eye movements occur.

Diplopia tests also present different images to the two eyes. These images may be identified by red–green (anaglyph) glasses or by mirrors. The Lancaster red–green test uses a screen marked in 2° increments viewed from a distance of 6.6 ft (2 m). The examiner projects a red or green line on the screen; the patient views through the anaglyph glasses and projects the appropriate colored line upon the examiner’s projected line. The results are recorded and the glasses reversed or the projecting wands switched. Torsion also could be evaluated by asking the patient to hold the projected line parallel to the examiner’s projected line; the plot will allow detection of torsional deviations along with horizontal and vertical deviations in different gazes.

The Hess screen contains illuminated red lights at fixed distances on a black screen; the patient places a green pointer light on the red lights while wearing anaglyph glasses. The glasses are reversed to test the other eye. Torsion cannot be detected with this test.

## EYE MOVEMENT EXAMINATIONS

### Introduction

Evaluation of ductions, versions, and vergences is essential to understand a patient’s eye movement system completely. A commonly accepted terminology system is given in [Table 11.3.1](#). *Ductions* are monocular eye movements, generally evaluated with the fellow eye occluded. Extreme gaze positions are investigated. In full and normal abduction, the temporal limbus touches the lateral canthus. Full adduction brings the junction of the nasal and middle corneal thirds to a position above the inferior tear punctum.<sup>7</sup> Each eye elevates 10 mm and depresses 5–7 mm. Tertiary gaze positions are also evaluated and compared with those in the fellow eye.

Measurements of eye movements may be performed by estimation or quantification by using the arc perimeter, Goldmann perimeter, or tangent screen. Rotations of 50° in all directions are considered normal.

*Versions* are binocular movements in which the eyes view in the same direction. They are used to enlarge the field of view and to bring the object of attention onto the fovea. Versions are either voluntary or involuntary. *Vergences* are binocular movements in which the eyes gaze in opposite gaze directions; these are slow movements made as part of the near synkinesis or to achieve better alignment to facilitate sensory fusion. Fusional vergence amplitudes (convergence amplitudes to correct an exodeviation,

TABLE 11.3.1 Eye Movement Terminology

	Terminology	Movement
Ductions	Adduction	Nasal rotation
	Abduction	Temporal rotation
	Depression	Downward rotation
	Elevation	Upward rotation
	Intorsion	Upper corneal pole rotates inward
	Extorsion	Upper corneal pole rotates outward
	Dextrocycloduction	Upper corneal pole rotates rightward
	Levocycloduction	Upper corneal pole rotates leftward
Versions	Dextroversion	Both eyes rotate to patient’s right
	Levoversion	Both eyes rotate to patient’s left
	Supraversion	Both eyes rotate upward
	Infraversion	Both eyes rotate downward
	Dextrocycloversion	Upper corneal poles of both eyes rotate to patient’s right
	Levocycloversion	Upper corneal poles of both eyes rotate to patient’s left
Vergences	Convergence	Both eyes rotate nasally
	Divergence	Both eyes rotate temporally
	Positive vertical vergence	Right eye rotates higher than left
	Negative vertical vergence	Left eye rotates higher than right
	Incyclovergence	Upper corneal poles of both eyes rotate inward
	Excyclovergence	Upper corneal poles of both eyes rotate outward

**Fig. 11.3.5 Forced Duction Testing.** The patient has left esotropia and limited abduction. The patient is abducting her left eye from a position of maximal adduction, and the examiner is attempting to abduct the eye farther than the patient can.

**TABLE 11.3.2 Normal Fusion Vergence Amplitudes**

Testing Distance (m)	Convergence (D)	Divergence (D)	Vertical Vergence (D)
6	14	6	2.5
0.025	38	16	2.5

divergence amplitudes to correct an esodeviation, etc.) may be measured by the introduction of increasingly strong prisms before one eye of the patient, who views an accommodation-controlling target. The patient reports when the image doubles or the examiner notes the sudden appearance of strabismus. The power of prism necessary to reach this “break” point is the vergence amplitude at a given testing distance in a given direction. The prism power is then reduced until the patient “recovers” fusion, usually within 2–4 D of the break point. The patient may generate accommodative convergence to aid fusion, especially at near fixation; the patient is asked to report target blur to the examiner, a signal that accommodative convergence is being generated.

Normal fusional vergence amplitudes are listed in Table 11.3.2.<sup>8</sup> Mellick studied fusional amplitudes in relation to age with two separate methods (prism stereoscope and synoptophore [a form of major amblyoscope]) and two targets. He found no significant influence of age.<sup>9</sup> To test fusional convergence, the prism is held base out before a patient’s eye; to test fusional divergence, the prism is held base in. Positive vertical vergence requires a base-down prism placed before the right eye, and negative vertical vergence requires one placed before the left eye.

## Mechanical Tests of Eye Movement Limitation

Patients who have duction limitations may suffer from paralysis or paresis, or mechanical restriction of full duction movement, or both. Forced duction testing and active force generation testing may help to differentiate these. In cooperative patients, these tests may be performed in the office, but in young or uncooperative patients, these tests are reserved for the operating room (see Chapter 11.13), when the patient is under local or general anesthesia.

### Forced Duction Test

The forced duction test is an attempt by the examiner to move a patient’s eye farther in a given direction than the patient can move it. Topical anesthetic is placed on the appropriate limbal location (generally 180° away from the duction limitation) with a small cotton swab, and the limbal conjunctiva is grasped firmly with a toothed forceps. The patient is asked to rotate the eye fully in the direction of the limited duction. An attempt then is made by the examiner to rotate the eye beyond the position attained by the patient while avoiding globe retraction (Fig. 11.3.5). Care must be taken not to abrade the cornea. Patients who have pure nerve palsy exhibit no restriction to full movement by the examiner; patients who have pure

**Fig. 11.3.6 Active Force Generation Test.** The patient has left esotropia and limited abduction. The patient abducts her left eye from a position of maximal adduction, and the examiner estimates the force of abduction through the forceps.

restriction (dysthyroid orbitopathy, entrapment of ocular contents after blowout fracture) exhibit restricted movements (termed *positive forced duction test*). Some patients initially have a pure nerve palsy, but contraction of the antagonist muscle results in secondary mechanical restriction of movement. Suction cup devices have been developed for examiners who are wary of using toothed instruments at the limbus; a cotton swab may be a sufficient tool in some patients, but because the tendency with use of the cotton swab is to push the eye posterior in the eye socket, this may relax the rectus muscles and hence give wrong impression of the duction test.

Forced duction testing of oblique muscles may be performed, but two forceps are used, and the globe is depressed forcibly into the orbit. This depression toward the orbit puts the oblique muscles on stretch while relaxing the rectus muscles. To test tension in the superior oblique tendon, the globe is grasped in the limbal meridian of the tendon (the 2:30 o’clock position in the right eye, the 10:30 position in the left) and 180° away. The globe is rocked clockwise and counterclockwise over the taut tendon and the tendon tension is evaluated; experience with normal tendons is essential to obtain an accurate evaluation. To test tension in the inferior oblique muscle, the globe is grasped at the 4:30 position limbus and 180° away in the right eye, at the 7:30 position limbus and 180° away in the left eye; the globe is rocked similarly and the muscle tension evaluated.

### Active Force Generation Test

Active force generation testing may be used to evaluate the ability of a muscle to move the eye against a resisting force. The forceps is placed at the limbus of the anesthetized globe in the meridian of the muscle whose duction is limited, and the patient requested to rotate the eye in the direction of the limited duction; the examiner judges through the forceps the relative amount of force generated. Strain gauges have been devised that enable quantitation of this force. Fig. 11.3.6 shows a patient who has maximal adduction in the left eye. The examiner can gauge the relative abduction strength as the patient attempts to move her eye to the left.

## Sensory Adaptations in Strabismus

## 11.4

Erika C. Acera, Gary R. Diamond<sup>†</sup>

**Definition:** Physiological adaptations to strabismus in order to avoid visual confusion or diplopia.

## Key Features

- Suppression.
- Monofixation syndrome.
- Anomalous retinal correspondence.

## VISUAL CONFUSION AND DIPLOPIA

## Introduction

Normal binocular vision is a process of fusing retinal images from each eye into a single three-dimensional visual perception. If binocular visual development is established early in an infant's life, it is maintained unless sight is lost in either eye. When an individual develops strabismus, the corresponding retinal elements in the two eyes are no longer directed toward identical objects. This puts the individual at risk for development of two specific visual phenomena, visual confusion and diplopia, both potentially quite uncomfortable. Visual confusion is the simultaneous perception of dissimilar objects that project on corresponding retinal elements (e.g., the two foveas). Diplopia is the perception of one object that projects on two different (noncorresponding) retinal areas (Fig. 11.4.1).

## Ocular Manifestations

Central confusion is physiologically eliminated in individuals of any age as the rod-free retinal areas cannot simultaneously perceive disparate targets. The fovea in the strabismic eye is immediately enveloped in a scotoma of roughly 2.5° diameter.<sup>1</sup> This can be demonstrated in oneself by manual displacement of one eye with a finger; there is an immediate decrease of visual acuity in that eye.

The onset of a new strabismus in children older than 7–9 years of age and in all adults causes diplopia. A patient with diplopia will fixate with the fovea of the straight eye and cortically inhibit the fovea of the deviated eye. The diplopic image results from a nonfoveal point being stimulated in the deviated eye and the image being localized to its corresponding visual field. If retinal correspondence is normal, patients with exotropia will experience heteronymous (crossed) diplopia, and patients with esotropia will experience homonymous (uncrossed) diplopia.

## Treatment, Course, and Outcome

Clinically, reports of visual confusion are rare, as the deviated fovea is suppressed. Acquired strabismus in the visually mature patient will experience diplopia unless it is controlled successfully by the fusional vergence system or by the occlusion of one eye or severely decreased visual acuity is present in one eye. Even patients who have acuity as low as 2/200 (0.6/60) may experience severe symptoms from visual confusion and diplopia. The ideal outcome for a patient with diplopia is the restoration of binocular single vision in all gaze positions. Nonsurgical interventions, such as eye exercises, prisms, optical blurring and/or occlusion, can be used indefinitely, if successful, or as a temporizing measure until strabismus surgery is needed. Botulinum toxin injections to the extraocular muscles to temporarily correct the strabismic deviation also have been used to eliminate diplopia.

<sup>†</sup>Deceased

**Fig. 11.4.1 Alignment of Foveal Images.** Normal alignment of a typical patient who has straight eyes fuses foveal targets. Right esotropia in a binocular patient results in visual confusion of foveal targets. This does not exist clinically, as the fovea in the turned eye cannot accept an image disparate from that seen by the fovea in the straight, fixing eye.

## SUPPRESSION AND ANOMALOUS RETINAL CORRESPONDENCE

## Introduction

Children younger than 7–9 years of age whose visual systems are still developing are usually able to achieve the sensory adaptations of suppression and anomalous retinal correspondence (ARC).<sup>2</sup> Suppression is the cortical mechanism used to eliminate the diplopic image caused by strabismus. Anomalous retinal correspondence is the adaptation to misaligned visual axes where the foveas are no longer functionally linked together in the visual cortex. Cortical reorganization of retinal relationships such that a peripheral retinal area of the deviating eye now shares a common visual direction occurs with the fovea of the straight eye. The foveas are no longer corresponding retinal points. These adaptations may develop rapidly or slowly after the appearance of strabismus.

## Ocular Manifestations

The cortical mechanism of suppression prevents diplopia from reaching consciousness during binocular visual activity and develops only during an immature visual system. Facultative suppression exists when the eyes are in the deviated state. As in the case of intermittent exotropia, suppression exists when the eyes are divergent and is not present when the eyes are

**Fig. 11.4.2 Esotropia and Exotropia.** Esotropia in the left eye—a nasal retinal suppression scotoma obviates central diplopia. Exotropia in the left eye—a temporal retinal suppression scotoma obviates central diplopia.

straight. In contrast, obligatory suppression is present at all times, whether the eyes are deviated or aligned. Constant monocular suppression not only results in poor binocular vision but may increase the risk of amblyopia.

Interestingly, the shape and size of the suppression scotoma are different in an esotrope compared with an exotrope.<sup>3</sup> An esotrope usually exhibits a small, round scotoma that envelops only the nasal retinal area within which the foveally viewed image in the aligned eye projects, although occasionally a somewhat larger, suppressed retinal area is demonstrated. Suppression scotoma in a patient with exotropia is much larger and encompasses the temporal retinal area on which the foveally viewed image in the aligned eye projects and, in addition, the entire area that extends to a vertical line that bisects the fovea (Fig. 11.4.2). Postulated explanations for this difference include developmental and teleological differences between the nasal and temporal hemiretinas, the intermittent and variable amplitude of many exodeviations, the constant nature of many esodeviations, and others; no explanation, however, is entirely convincing.

Anomalous retinal correspondence restores some sense of binocular cooperation with limited fusion and stereoscopic capabilities in the presence of a heterotropia. Therefore, patients with ARC do not experience diplopia. In the development of ARC, the normal sensory development is replaced only gradually and not always completely.

## Diagnosis and Ancillary Testing

There are a variety of tests to assess a patient's sensory status and to help identify the type of sensory adaptation, if present. It is important to note that the degree of the dissociative nature of the tests may influence a patient's response and perhaps give varying responses regarding the state of retinal correspondence. Tests that are least disruptive to the symmetry of binocular input (i.e., minimal dissociation) are more likely to give evidence of ARC. For example, a positive ARC response may be shown using the Bagolini lenses but may not persist with the more dissociative after-image test. The inconsistency of responses on the sensory tests has been interpreted as how firmly established the cortical adaptation is.<sup>4</sup> Because the depth of the sensory rearrangement can vary widely, an individual can test positive for both normal retinal correspondence (NRC) and ARC.

## Treatment, Course, and Outcome

Suppression is a barrier to fusion. Management of suppression, therefore, involves the treatment of the strabismus itself via refractive error

### BOX 11.4.1 Features of Monofixation Syndrome

#### Consistent With Normal Retinal Correspondence

- Presence of measurable fusional vergence amplitudes
- Presence of stereopsis (to 67 arc seconds) in many
- Relatively stable alignment
- Demonstrable peripheral fusion
- No measurable heterotropia in many

#### Consistent With Anomalous Retinal Correspondence

- Small heterotropia in some
- Lack of stereoscopic appreciation in some

### BOX 11.4.2 Older Terms for Monofixation Syndrome

Monofixational phoria  
Microtropia  
Microstrabismus  
Esotropic flick strabismus  
Small-angle strabismus

correction, occlusion, or pharmacological penalization to overcome any amblyopia that may be present and alignment of the visual axes to permit simultaneous stimulation of corresponding retinal elements. Antisuppression exercises are contraindicated if the patient does not elicit fusional potential in an effort to prevent intractable diplopia.

Anomalous retinal correspondence is a sensory adaptation to abnormal ocular alignment in an attempt to recover binocular cooperation. It should be noted that the quality of binocularity of a patient with ARC is inferior to that of the binocular interaction in NRC. The presence of ARC is of clinical significance when planning strabismus surgery. Patients may become aware of paradoxical diplopia if the surgical target angle does not take into account the patient's ARC status. (i.e., crossed diplopia in patients with esotropia and uncrossed diplopia in patients with exotropia). This postoperative paradoxical diplopia is usually transient. Nowadays, ARC is rarely seen clinically because of the early screening and treatment of childhood strabismus.

## MONOFIXATION SYNDROME

### Introduction

Many binocular patients who have a small or absent heterotropia (up to 8Δ esotropic or exotropic and 2Δ vertically up or down) and possible superimposed heterophoria exhibit monofixation syndrome (MFS), show a sensory state that comprises features of both normal retinal correspondence and ARC (Box 11.4.1). Initially known by many terms, each of which explains one sensory or motor component of the complete syndrome (Box 11.4.2), the generally accepted name MFS emphasizes the essential feature of this syndrome, the presence of peripheral fusion without central fusion.<sup>5</sup> This means that only one rod-free retinal area (fovea) views at a given time.

Tychsen<sup>6</sup> has shown in cortical area V1 of macaque monkeys that horizontal axons of about 7 mm in length could join receptive fields about 2.5° or 4.4 prism diopters apart. Two neurons could join fields about 5.0° or 6.6 prism diopters apart. Thus, the maximal tropia that permits peripheral fusion is explicable as a combination of V1 neuron reach and V1 topography.<sup>6</sup>

The syndrome may develop spontaneously by unknown means, may be caused by anisometropia, is the best-expected sensory state in almost all patients who have infantile strabismus after successful surgical alignment, and is found in patients who have acquired unilateral organic foveal lesions (e.g., toxoplasmosis), although in the last instance, the scotoma is usually larger. The absence of bifoveal fusion and reduced stereoacuity also has been reported in adults with long-standing constant strabismus,<sup>7</sup> long-standing surgically induced monovision,<sup>8</sup> and in the delayed removal of dense adult onset cataracts.<sup>9</sup>

Central fusion (bifoveal viewing with the possibility for superb stereoscopic appreciation) may occur in the presence of very minimal deviation of the visual axes, less than that detectable by cover testing, and is termed fixation disparity; it measures roughly 14 minutes of arc (perhaps 0.5Δ) and is present in most individuals.<sup>10</sup> It should not be confused with MFS.

**Fig. 11.4.3 Monofixation Syndrome With No Heterotropia.** Note the central scotoma that envelops the area seen by the left fovea and fusion of peripheral information.

## Ocular Manifestations

Patients who have MFS demonstrate an absolute, facultative, central scotoma that usually measures  $2.5^{\circ}$ – $3^{\circ}$  in diameter, and, like a suppression scotoma seen in binocular patients who have childhood-onset strabismus and larger heterotropias, it is present only when a given fovea is not fixing (Fig. 11.4.3).

## Diagnosis and Ancillary Testing

Peripheral fusion and demonstrable fusional vergence amplitudes (often of a normal amount) usually are demonstrable in patients who have MFS and provide generally stable alignment.<sup>11</sup> Presumably, the expanded nature of the peripheral Panum's fusional area permits peripheral fusion to develop despite a small heterotropia (Fig. 11.4.4). Perhaps this reflects the greater than one-to-one linkage between peripheral retinal photoreceptors and ganglion cells. Stereoscopic ability often is found but is rarely better than 67 seconds of arc, as only one fovea is used in binocular viewing.<sup>12</sup> Note that the sensory status of patients who have MFS is the same whether or not a small heterotropia exists, although those who have large, superimposed heterophorias may sometimes have asthenopic symptoms.

Sensory testing shows peripheral without central fusion, possible stereoscopic appreciation (although never to normal limits), and generally normal fusional vergence amplitudes. If the patient has a heterophoria superimposed on a small heterotropia, alternate cover testing demonstrates larger strabismus than does cover/uncover or simultaneous prism-and-cover testing.<sup>13</sup>

Patients who have MFS exhibit sensory characteristics closer to normal retinal correspondence than ARC, that is, the presence of fusional vergence amplitudes and possible gross stereoscopic appreciation, although those who have a small heterotropia do not have precise alignment of corresponding retinal elements.<sup>14</sup> Cover testing shows roughly 22% without a manifest or latent deviation, 34% with heterophoria only, and 44% with heterotropia and superimposed heterophoria, occasionally up to  $20\Delta$ . Only MFS permits the existence of a measurable heterotropia and superimposed heterophoria.<sup>15</sup>

## Course and Outcome

The absence of simultaneous foveal viewing means that young patients are at risk for the development of amblyopia, and approximately two-thirds do become amblyopic—90% if they also have a heterotropia. In the absence of

**Fig. 11.4.4 Monofixation Syndrome With  $4\Delta$  Right Esotropia.** Note the right central scotoma that prevents perception of the plane and helicopter under binocular viewing conditions and fusion of peripheral information (balloons). The horopter is an infinitely thin surface in space that contains all the object points that project to corresponding retinal points. It is surrounded by Panum's fusional area, within which objects in space can be fused, even though they project onto noncorresponding retinal points.

anisometropia, three-fourths of patients with MFS have amblyopia. In the case of successfully aligned infantile esotropes, of those who have MFS, one-third have amblyopia. As in the treatment of all amblyopia, the earlier the treatment is started the better the outcome in improving vision.

Once MFS is present, it is not possible to advance to bifoveal fusion via eye exercise, prisms, surgery, or any other methods. Despite being relatively stable, this condition may decompensate, causing an increase in heterotropia resulting in diplopia. Reducing the angle of strabismus to within "monofixation" range, by optical or surgical means, will eliminate the diplopia.

# Sensory Status in Strabismus

Gary R. Diamond<sup>†</sup>, Nicola Freeman

# 11.5

## Definitions:

- **Fusion:** cortical integration of slightly dissimilar images perceived by the two eyes into a unified percept.
- **Horopter:** the locus in space representing the intersection of all points that stimulate corresponding retinal points.
- **Panum's fusional area:** area in space surrounding the horopter in which objects can be fused.
- **Stereopsis:** a form of depth perception that demands binocular vision and usually sensory fusion.
- **Monofixation syndrome:** a form of binocular vision found in many patients who have small amounts of strabismus that permits peripheral fusion, stereopsis, and alignment stability.

## Key Features

- Subjective tests for binocular vision and retinal correspondence are an important part of every patient's examination.
- Monofixation syndrome can be reliably diagnosed only with sensory testing.

## INTRODUCTION

Binocular patients who develop strabismus before the age of 7–9 years usually develop the sensory adaptations of suppression and anomalous retinal correspondence to obviate diplopia and visual confusion (see Chapter 11.4). Older patients who develop strabismus for the first time suffer from diplopia and visual confusion as long as vision remains in both eyes, until the eyes are aligned or the patient learns to ignore one image. Nonbinocular patients (or those who perceive vision with one eye at a time) are not troubled by symptoms of double vision if their eyes become strabismic.

Clinical testing of sensory status in patients with strabismus is easier to understand after the basic physiology of sensory fusion and stereopsis has been understood.

## SENSORY FUSION

Sensory fusion is the cerebral cortical integration of the slightly dissimilar images perceived by the two eyes into a unified perception. If images are sufficiently dissimilar, they cannot be fused; examples are red and green variants of the same object or lines seen vertically by one eye and horizontally by the other. Binocular rivalry usually occurs under these conditions, and a varying perception is obtained. Motor fusion with vergence amplitudes, and even stereopsis, may be produced by rivalrous stimuli in the absence of sensory fusion. Such stimuli are fortunately uncommon in daily life but are most useful when assessing the sensory status of the visual system.

A retinal element is a small retinal patch that has an associated directional value. The fovea's directional value is defined subjectively as straight ahead; peripheral retinal elements possess directional values in other orientations. Corresponding retinal points are a pair of retinal elements, one in each eye, that have the same directional value. Comfortable single binocular vision occurs when objects in the binocular field stimulate corresponding retinal points and the higher cortical function—termed *sensory fusion*—occurs.

**Fig. 11.5.1 Panum's Fusional Area.** The left eye fixates a square target, and a search object visible only to the right eye is moved before and behind this target. The ellipse of retinal area, for which typical dimensions are given for the parafoveal area, is the projection of the Panum's fusional area. Diplopia is not perceived for two targets within this area.

The locus in space that represents the intersection of all points in space that stimulate corresponding retinal points is termed the *horopter*. Interestingly, sensory fusion still occurs if the object that projects on a retinal element in one eye projects on a range of elements that surrounds the corresponding retinal element in the second eye. The area in space that projects from this range of elements in the second eye that intersects with the projection from the retinal element in the first eye is termed *Panum's fusional area* (Fig. 11.5.1). Panum's fusional area surrounds the horopter anteriorly and posteriorly; it permits fusion to take place when exact retinal correspondence does not occur. The binocularly perceived object imaged on noncorresponding retinal loci, but fused within Panum's fusional area, is perceived to have one subjective visual direction. The foveal Panum's area is circular, of diameter about 14 minutes of arc; thus, an object projected on the fovea of one eye may be displaced by this amount, and the patient still maintains bifoveal vision. The size of Panum's fusional area increases toward the retinal periphery (see Fig. 11.5.1), but the ultimate size and shape depend on the temporal and spatial frequency of the patient's alignment drift when fixing on a stationary target.<sup>1</sup>

Objects in front of or behind Panum's fusional area stimulate physiological diplopia, which is not usually noted but may, in turn, stimulate fusional vergence eye movements. The horopter shape may be defined in a pair of perfectly spherical eyes that have refractive seats at the nodal points of each eye as the locus of points of zero vertical disparity relative to the fixation points. In a horizontal plane, the horopter, which includes the fovea, is the Vieth–Müller circle (Fig. 11.5.2).<sup>1–3</sup> In a living animal visual system, the horopter is flatter (the Hering–Hellebrand horopter deviation). The vertical horopter tilts away from the observer, who stands on the horopter; the inclination is a function of fixation distance.<sup>3,4</sup>

## DEPTH PERCEPTION AND STEREOPSIS

Depth perception may occur without binocular vision because it is dependent on both monocular and binocular clues. Stereopsis is a form of depth perception that demands binocular vision and usually sensory fusion but, under certain conditions, may be stimulated by rivalrous objects whose images cannot be fused. Stereopsis is the perception of depth stimulated by objects that possess horizontal disparity, with one object usually located

<sup>†</sup>Deceased

**Fig. 11.5.2 Vieth-Müller Circle.** If the eyes are assumed to be spherical with rotational centers at the nodal points, all points in space that have a zero disparity fall on this circle. Angle  $\alpha_1$  = angle  $\alpha_2$ ; thus, equal retinal distances map into equal angles in space in this idealized system.

in front of or behind the fixation point. Horizontal disparity alone is sufficient to stimulate the stereoptic perception. Visual contours are not necessary, and disparity may be stimulated by random dots.<sup>5-7</sup> *Stereoacuity*, the disparity threshold at which a depth difference may just be appreciated, is best at the fovea and depends on the level of visual acuity in each eye. Stereoacuity dissipates rapidly into the peripheral visual field and with increasing object distance<sup>8</sup> and is proportional to interpupillary distance. Under ideal conditions, human foveal stereoacuity may be 10 seconds of arc.<sup>9,10</sup>

## CLINICAL TESTING

The clinician must determine the sensory status of each patient, specifically whether the patient is binocular and if so, whether the patient has normal retinal correspondence (NRC) or anomalous retinal correspondence (ARC) and suppression (see Chapter 11.4). Binocular patients who have constant tropias measurable on cover testing may exhibit NRC with diplopia and visual confusion, ARC and suppression, or monofixation syndrome (MFS). MFS possesses features of both NRC and ARC but is considered closer to the former.

Asymptomatic patients who have tropias  $>8\Delta$  horizontally or  $>4\Delta$  vertically usually have ARC and suppression, although these may be difficult to demonstrate. Asymptomatic binocular patients who have smaller tropias, or a smaller tropia with superimposed phoria, usually have MFS.

Many sensory tests are available to the busy clinician, but access to and understanding of just a few enable evaluation of the patient's sensory status. It is important to perform sensory testing at the beginning of the examination; prolonged monocular occlusion to evaluate visual acuity may dissociate the eyes and confound determination of the patient's ambient sensory status.

## Testing for Binocularity (Simultaneous Perception)

Many tests require simple tools to demonstrate binocularity. Holding a red lens before one eye and presenting a white light detects perception of two lights, red and white, in patients who have NRC and diplopia. Prisms may be used to project one light beyond the bounds of a suppression scotoma in patients who have ARC and suppression or NRC-MFS. Commercially available Polaroid projection slides, when viewed through polarized lenses, present one-half of an optotype line to each eye; binocular patients view the entire line, whereas nonbinocular patients view the half perceived by the foveating eye only. Prismatically, overcorrection of a patient with strabismus elicits diplopic symptoms, which proves the presence of binocular vision.

The Worth four-dot test is an array of four round targets ("dots"), usually presented with the red dot above two green dots that, in turn, are above one white dot. Distance (Fig. 11.5.3) and Near (Fig. 11.5.4) Worth four-dot targets are used. The diameter of the target array subtends  $1.25^\circ$  at 6 m and  $6^\circ$  at 33 cm. The targets are viewed through red-green (anaglyph) glasses, and the patient describes the perception to the examiner or simply counts the lights viewed. Binocular patients perceive red and green lights

**Fig. 11.5.3 Distant Worth Four-Dot Target.** This is fixed to a wall, traditionally with the red dot placed at the top.

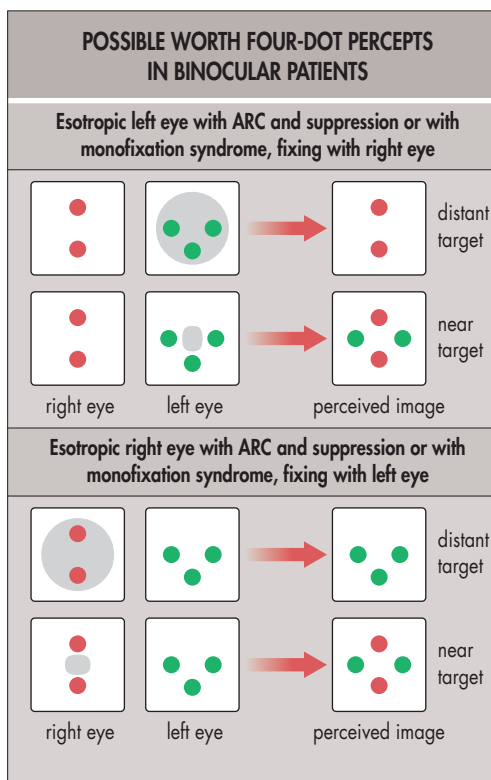

**Fig. 11.5.4 Near Worth Four-Dot Target and Anaglyph Glasses.** The near target is brought to the face to elicit a binocular response in patients who have strabismus and large scotomas.

simultaneously, but the near wand must be held very close to a patient with a large strabismic deviation to project the target beyond the bounds of a suppression scotoma (Fig. 11.5.5). Nonbinocular patients see two red or three green lights at all testing distances (Fig. 11.5.6).

Baglioli lenses are finely ruled plano lenses that give a streak appearance to a point light source perpendicular to the ruled direction. The lenses are placed in orthogonal orientation (traditionally at  $135^\circ$  right eye and  $45^\circ$  left eye; Fig. 11.5.7) in a trial frame, and the patient views a light at distance fixation. Binocular patients perceive an "X" figure or, if a suppression scotoma exists, one complete line and the peripheral elements of the second. Nonbinocular patients see only one entire line.

Haploscopes, for example, the major amblyoscope, may present slightly different but fusible images to each eye; if portions of each image are perceived, the patient is binocular. The viewing tubes may be displaced to the strabismic angle, if such exists, or the tubes may be kept in the straight position and targets used that are large enough to project beyond the suppression scotoma.

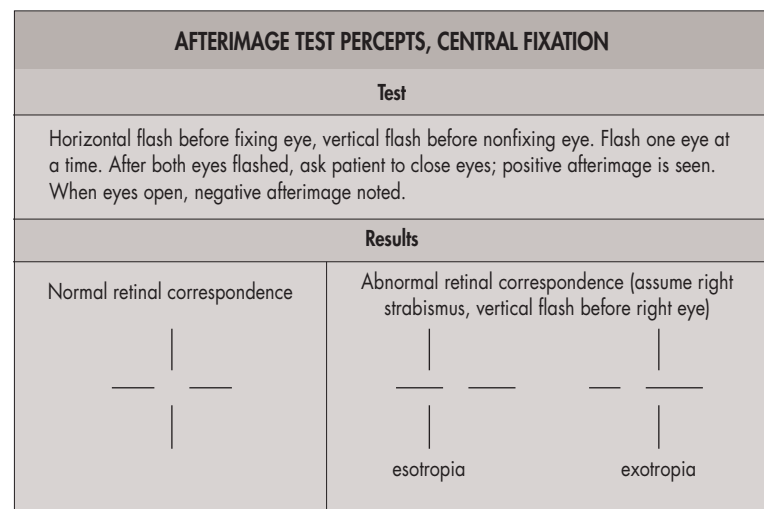

**Fig. 11.5.5 Possible Worth Four-Dot Percepts in Binocular Patients.** Note the similar distant responses in patients who have esotropia with abnormal retinal correspondence (ARC) and suppression and in those who have monofixation syndrome. Patients who have exotropia with ARC and suppression give the same responses, but the suppression scotoma is larger and shaped somewhat differently (see Fig. 11.4.2). The red lens is over the right eye and the green lens over the left eye.

**Fig. 11.5.6 Possible Worth Four-Dot Responses in Patients Who Do Not Have Binocularity.** The red lens is over the right eye and the green lens over the left eye.

**Fig 11.5.7 Bagolini Lenses in a Trial Frame.** Striations placed at 75 degrees right eye and 135 degrees left eye.

**Fig. 11.5.8 Afterimage Test Percepts, Central Fixation.** Shown are those possible in patients who have central fixation and binocular vision.

### BOX 11.5.1 Retinal Correspondence Tests (Listed Most Sensitive to Least Sensitive)

Afterimage test

## Tests of Retinal Correspondence

Many of the preceding tests may be used in binocular patients to diagnose ARC and suppression, NRC bifoventality, or NRC-MFS at a given testing distance at a given moment. As ARC exists only under binocular testing conditions, some tests may yield an ARC response at a given moment, whereas other tests yield an NRC response, depending on the room illumination and the length of time ARC has been present. Tests that confound correctable single binocular vision and that poorly reproduce ordinary binocular viewing conditions demonstrate ARC later compared with tests that closely simulate typical binocular viewing conditions. Retinal correspondence tests more commonly used in clinical practice are listed, by depth of abnormal correspondence, in [Box 11.5.1](#).

The afterimage test is most removed from ordinary binocular viewing and the most dissociating of all commonly performed retinal correspondence tests; an ARC response on this test declares the ARC to be deep seated. An afterimage (positive in dim illumination, negative in bright) is imprinted on each retina in turn with a photographic flash device. The fellow eye is covered during the flash. Usually, a vertical flash is presented to one eye and a horizontal flash to the other. The fovea is protected by a central mask with fixation target and thus “labeled” as the center of an afterimage line. An NRC response yields a cross pattern ([Fig. 11.5.8](#)) because the fovea in each eye retains the straight-ahead directional value. A crossed heteronymous localization occurs in ARC with esotropia, as the straight-ahead directional value lies in the nasal retina of the strabismic eye; the fovea has a temporal directional value.<sup>11</sup> In patients who have ARC and exotropia, the afterimage perception is an uncrossed homonymous localization.

In patients who have ARC, suppression, and NRC-MFS, the Worth four-dot test demonstrates suppression of one eye when presented with a distant Worth target and fusion of lights of the near Worth target (see [Fig. 11.5.5](#)). The Worth four-dot test thus cannot be used to differentiate ARC from NRC easily.<sup>12</sup>

Clinicians who have access to a major amblyoscope (synoptophore) may set the tubes at the objective angle of strabismus; if the targets are superimposed, NRC exists. Crossed diplopia occurs in patients who have ARC and esotropia and uncrossed diplopia in patients who have ARC and exotropia. An “angle of anomaly” is defined when the patient moves the tubes until the targets are superimposed; this subjective angle equals the objective angle in “harmonious” ARC and is less or greater in “unharmonious” ARC.

The Bagolini lens test most closely simulates ordinary viewing and is the least dissociating of all retinal correspondence tests.<sup>13</sup> Central (foveal)

POSSIBLE BAGOLINI LENS PERCEPTIONS, CENTRAL FIXATION				
Test				
Right eye lens at 135 in trial frame, left eye lens at 45. Fixate on distant light in semidarkened room.				
Closest sensory test to normal viewing, first to exhibit abnormal retinal correspondence (ARC) strabismus, first to revert to normal retinal correspondence (NRC) when eyes aligned.				
Results				
Cover–uncover test irrelevant	No binocularity, right eye fixing		No binocularity, left eye fixing	
No shift on cover–uncover testing (no tropia)	NRC bifoveal		NRC monofixation, left eye fixing	
Shift on cover–uncover testing (tropia)	$\leq 8\Delta$ NRC monofixation, left eye fixing		$> 8\Delta$ ARC, left eye fixing exotropia	
	$> 8\Delta$ ARC, left eye fixing esotropia

fixation must be assumed and the alignment of the eyes known; possible outcomes are given in Fig. 11.5.9.

Stereopsis Tests

Clinically useful stereopsis tests provide slightly different views of the same target to each eye. A unique view is created by either Polaroid filters (e.g., Titmus, Lea symbols Butterfly Stereo Acuity, Wirt, Randot) or anaglyph (red and green) glasses (e.g., TNO test).

The Titmus stereotest (Fig. 11.5.10) provides disparity in the range 3000 seconds of arc at 40 cm testing distance (fly wings above background) to 40 seconds of arc (ninth circle). Younger children may respond to the depth

Fig. 11.5.11 TNO stereotest with anaglyph (red and green) glasses.

Fig. 11.5.13 Frisby stereotest.

illusion of three sets of five animals, one of which appears to float above the background (400, 200, 100 seconds of arc). The TNO stereotest (Fig. 11.5.11) uses random-dot stereograms viewed through anaglyph glasses and contains disparities in the range 480–15 seconds of arc. Children who reject polaroid or anaglyph glasses may be tested by using the Lang test<sup>14</sup> (Fig. 11.5.12), in which random-dot stereograms are presented through a cylinder grating that overlies the target or the Frisby stereotest (Fig. 11.5.13), which consists of three plates that permit stereoacuity measurement in the range of 600–20 seconds of arc.

TABLE 11.5.1 Synopsis of Sensory Testing in Strabismus

Test	NRC–Bifoveal	NRC–Monofixation	Abnormal Retinal Correspondence	Diplopia	No Binocularity
Worth four-dot, distance (6 m)	4 dots	2 or 3 dots	2 or 3 dots	5 dots	2 or 3 dots
Worth four-dot, near (40 cm)	4 dots	4 dots	4 dots	5 dots	2 or 3 dots
Stereo	None to 14 sec arc	None to 67 sec arc	None	None	None
The Worth four-dot test and stereotest can be used to define a patient's sensory status. Appreciation of four lights on the Worth test at any testing distance signifies binocular vision. Appreciation of four distant lights demands normal retinal correspondence (NRC) and bifoveality, as does recognition of less than 100 seconds of arc stereoacuity. Any level of stereoptic appreciation signifies NRC at that moment at that testing distance.					

Test for Monofixation Syndrome

One feature of this syndrome (see Chapter 11.4) is a small, round scotoma that surrounds the fovea of one eye under binocular viewing conditions. As the patient views a distant target, a 4Δ prism, usually held base out, is introduced before one eye. If held before the fixing eye, both eyes will saccade to the new target position in the direction of the prism's apex. A slower fusional vergence movement in the fellow eye in the opposite direction follows. However, when the prism is held before the nonfixing eye, there is no saccade because the displaced image falls within the scotoma and, therefore, is not perceived.<sup>15</sup> The test must be performed with the prism held before each eye. It is possible that some patients may switch fixation as the prism is introduced, and in this case no saccadic shift will then be observed.

In summary, the busy clinician may best determine the sensory status of most patients by using two straightforward and easily available tests—the Worth four-dot test and the Titmus stereotest. A summary of sensory testing interpretation using these commonly available testing devices is given in Table 11.5.1.

# Esotropia

Michael Kinori, Shira L. Robbins

# 11.6

**Definition of Infantile Esotropia:** Inward deviation of the visual axes, with an onset before age 6 months.

## Key Features of Infantile Esotropia

- Esotropia typically greater than  $30\Delta$  present before 6 months of age.
- Cross-fixation.
- Little to no binocular vision.
- Normal refractive error for age (between +0.50 and +3.00).
- Initially, similar deviation at distance and near fixation.

## Associated Features (Often Appear After the First Year of Life)

- Inferior oblique muscle overaction.
- Dissociated vertical deviation.
- Fusion maldevelopment nystagmus (previously known as *latent nystagmus*).
- Amblyopia in about one-third of patients.

**Definition of Accommodative Esotropia:** Inward deviation of the visual axes caused by the focusing efforts of the eyes as they try to see clearly. Patients typically have hyperopia and/or high accommodative convergence-to-accommodation (AC/A) ratio.

## Key Features of Accommodative Esotropia

- Initially intermittent acquired esotropia.
- Esotropia larger at near than distance fixation.
- Age of onset usually between 18 months and 3 years.

## Associated Feature

- Typically hyperopic, but patients who have a high AC/A ratio may have any refractive error.

**Definition of Duane's Syndrome:** Congenital miswiring of the medial and/or lateral rectus muscles.

## Key Features of Duane's Syndrome

- Retraction of the affected globe(s) on attempted adduction.
- Limitation of abduction, adduction, or both.
- Abnormal head posture.
- Present from birth; however, often noticed later in infant/toddler years.

## Associated Features of Duane's Syndrome

- Elevation (upshoot) or depression (downshoot) of the globe on attempted adduction.
- Esotropia (or exotropia in some patients), rarely larger than  $30\Delta$ .

## INTRODUCTION

Esotropias represent the most common form of strabismus and include infantile, accommodative, cyclical, and nonaccommodative forms. They also are seen more frequently in children with neurological impairment or vision deficit (sensory esotropia) and in some patients who have Duane's and Moebius' sequence, sixth cranial nerve palsy, and thyroid disease associated strabismus.

## INFANTILE ESOTROPIA

### Introduction

Infantile esotropia was previously termed *congenital esotropia*. "Congenital esotropia" is a misnomer because in very few cases, if any, esotropia is present at birth.<sup>1</sup> Infantile esotropia is defined as esotropia that presents before 6 months of age (Fig. 11.6.1). Many normal infants will have an intermittent esotropia or exotropia in the first weeks of life that is thought of as developmental and disappears between ages 2 and 4 months. Prospective studies have determined that this is the age at which infantile esotropia is first noted. Among younger infants, it cannot be predicted who will develop infantile esotropia by age 2–4 months.<sup>1</sup>

### Epidemiology and Pathogenesis

The incidence of infantile esotropia is roughly 1% in most series and may be more common in children who have neurological disorders.<sup>2</sup> Gender and racial distributions are equal. Concordance in one series was 81% in monozygous twins and 9% in dizygous twins.<sup>3</sup> It is common to find some form of strabismus in other members of the proband's family.

### Ocular Manifestations

Amblyopia occurs in 25%–40% of patients, but the majority "cross-fixate" (i.e., use the right eye to fix across the nose to view objects to the left of the patient, and vice versa) (Fig. 11.6.2).<sup>4</sup> A child who does not have amblyopia

**Fig. 11.6.1 Infantile Esotropia.** The child is fixing with her left eye; note the temporally decentered light reflex in the right eye.

**Fig. 11.6.2 Congenital Esotropia and Cross-Fixation.** The infant uses the right eye to view left, and vice versa. Note that the infant uses his left eye to fix across the nose to view objects on his right side.

**Fig. 11.6.3 Bilateral Overelevation in Adduction.** Although the patient has orthophoria in primary gaze, she has bilateral overelevation of the globe in adduction caused by inferior oblique imbalance.

**Fig. 11.6.4 Dissociated Vertical Deviation in the Right Eye.** The patient's right eye drifts upward with dissociation. When the patient fixates with the right eye, no hypodeviation is seen in the left eye. (Reproduced with permission from Cheng KP, Biglan AW, Hiles DA. Pediatric ophthalmology. In: Zitelli BJ, Davis HW, eds. Atlas of Pediatric Physical Diagnosis. 2nd ed. New York: Gower Medical Publishing; 1992. p. 19.1.)

#### BOX 11.6.1 Dissociated Vertical Deviation Compared With Inferior Oblique Overaction

##### Dissociated Vertical Deviation

Present in all gaze positions  
Does not obey Hering's law  
Slow floating elevation, abduction,  
excyclotorsion movement  
Not associated with A- or V-pattern

##### Inferior Oblique Overaction

Present in adduction only  
Obeys Hering's law  
Rapid elevation and abduction  
movement  
Often associated with V pattern

switches fixation at the midline as an object is brought from one side to the other and does not maintain fixation or adopt a progressive head turn. This phenomenon might cause the examiner to believe that a true abduction deficit exists and pursue an unnecessary workup for sixth cranial nerve palsy. In most cases, however, when one eye is covered, full abduction can be elicited in the uncovered eye.<sup>5</sup> The “doll's head” maneuver is helpful to demonstrate true abduction ability. Generally, the deviation is greater than 30Δ and comitant, measuring roughly the same in all gaze positions, both distant and near gazes.

Inferior oblique muscle involvement is noted in up to 75% of patients, with an onset most frequently during the second year of life; it may be unilateral or bilateral (Fig. 11.6.3).<sup>6</sup> Early surgical correction of esotropia does not prevent the later development of inferior oblique imbalance. This should be differentiated from dissociated vertical deviation (DVD), which also occurs in roughly 75% of these patients and has similar onset patterns<sup>7</sup> (Fig. 11.6.4). DVD may be manifest or latent, can be very asymmetrical, and may present as any combination of slow elevation, abduction, and excyclotorsion (Box 11.6.1). Less commonly, the dissociated abduction is more prominent than elevation, and in that case, it is termed *dissociated horizontal deviation* (DHD). A dissociated torsional deviation (DTD) can be seen as a few nystagmus beats. Although its cause is unknown, DVD may represent a primitive eye movement pattern uncovered by deficient fusion.

Fusion maldevelopment nystagmus (FMN), formerly known as *latent nystagmus* with fast phase toward the unoccluded eye, is found in approximately 50% of patients.

Asymmetrical monocular pursuit is a feature of infantile esotropia, as measured by optokinetic nystagmus (OKN). Temporal-to-nasal pursuit is favored; patients who have infantile esotropia show poor nasal-to-temporal OKN regardless of the degree of stereopsis or the timing of surgery.<sup>8</sup>

Many young children sent to ophthalmologists by pediatricians for esotropia have pseudo-esotropia, an illusion caused by a wide and flat nasal bridge, wide epicanthal folds, and the ability to converge to very close distances (Fig. 11.6.5A).<sup>9</sup> In the Asian population, where a flat nasal bridge and wide epicanthal folds are more common features, pseudoesotropia is

**Figure 11.6.5 Pseudoesotropia.** (A) Wide flat nasal bridge with prominent epicanthal folds covers the nasal sclera giving the impression of an esotropia. However, the corneal light reflexes are centered in each eye. (B) Patient does not appear cross-eyed with elimination of the prominent epicanthal folds.

#### BOX 11.6.2 Differential Diagnosis of Infantile Esotropia

Early-onset accommodative esotropia  
Nystagmus blockage syndrome  
Moebius' sequence  
Duane's syndrome  
Congenital sixth cranial nerve palsy  
Cyclic esotropia  
Esotropia associated with visual loss in one eye (sensory esotropia)  
Neurological impairment  
Strabismus fixus and other fibrosis syndromes

more likely. A recent study found that the positive predictive value of referral for infantile esotropia in children of Chinese descent was only 5.9% (as opposed to 36% in non-Chinese children).<sup>10</sup>

### Diagnosis

Cover test measurements to measure the angle of strabismus may be difficult in very young children. The light reflex tests (Hirschberg and Krimsky) are easier to perform in infants. A variation of the light reflex test in which the deviation is neutralized by prisms held apex to apex before both eyes may be required if the angle of strabismus is very large. The deviation tends to be constant but may vary; spontaneous resolution may occur if the deviation is small (<40Δ) or intermittent.<sup>11</sup> Refractive errors are typically similar to those of normal children of the same age.

In older children with surgically corrected or uncorrected infantile esotropia, FMN may confound attempts at monocular acuity measurement; fogging one eye with plus lenses, a translucent occluder, or anaglyph (red-green) lenses may provide a more accurate acuity measurement in the face of FMN.

Side-gaze observations by nonophthalmologists may be particularly deceptive in the case of pseudo-strabismus, as the adducted eye is buried easily under the skin fold. Hirschberg's light reflexes may demonstrate alignment to the parents, as can elevation of the nasal bridge skin away from the face to alter the facial appearance temporarily (see Fig. 11.6.5B).

### Differential Diagnosis

The differential diagnosis of infantile esotropia (Box 11.6.2) includes the entities discussed in detail later. The nystagmus blockage (compensation) syndrome, in the opinion of some investigators, accounts for a significant segment of the young population with large-angle, early-onset esotropia.<sup>12</sup> These patients have a large esotropia and nystagmus at a young age. The nystagmus is of minimal amplitude in adduction and maximal in abduction.<sup>13</sup> Therefore, the patient makes a continuous effort to maintain both eyes in adduction through the use of convergence, and it may be

impossible to neutralize the esodeviation by using prisms held before one or both eyes. This is in contrast to nystagmus associated with the common form of infantile esotropia (FMN), which presents in equal degrees in all gaze positions. Various series imply that nystagmus blockage syndrome affects 10%–12% of patients with infantile esotropia, but many investigators believe that it is much less common. Sixth cranial nerve palsies need to be considered in the transient newborn form, which often resolves spontaneously over a few days or weeks as well as the more common acquired postviral or postimmunization form.

Treatment

The theoretical goals of treatment include the following:

- Excellent visual acuity in each eye.
- Perfect single binocular vision in all gaze positions at distance and near.
- A normal aesthetic appearance.

All of the above are obtainable except for perfect single binocular vision (with rare exceptions)<sup>14</sup> because these patients, even with early treatment, do not view with both foveae simultaneously. However, as discussed later, most obtain peripheral fusion with the monofixation syndrome and generally stable alignment. Other reported benefits of successful surgical alignment include improvement in fine motor skills, enlarged binocular visual field, and even heightened bonding between the parents and the child.

Amblyopia traditionally is treated preoperatively for multiple reasons: (1) Compliance is usually better as families are more motivated to treat when they can see the strabismus; (2) visual behavior may be evaluated more easily (the eye moves to take up fixation in the presence of a large strabismus); (3) amblyopia responds more quickly in a younger child; and (4) postoperative occlusion treatment would interfere with the potential development of binocularity. Amblyopia associated with infantile esotropia is amenable to treatment. With the appropriate optical correction and occlusion therapy (or equivalent) adjusted throughout the first years, 20/20 vision can be achieved in most patients.<sup>15</sup> The impact of treatment of refractive errors less than +2.00 D usually is minimal. Larger refractive errors are corrected, and the deviation is remeasured because postoperative exotropia may occur if surgery is performed on uncorrected, highly hyperopic eyes denoting an accommodative esotropic component.

When infantile esotropia is left untreated, patients do not display binocular vision of any type when they become old enough to cooperate for testing of their visual sensory status. The primary goal of surgical treatment at this age is to align the eyes sufficiently to stimulate the development of some binocularity. This binocularity usually fulfills the criteria for monofixation syndrome, as defined by Parks,<sup>16</sup> and is generally a stable alignment.<sup>17,18</sup> The works of Birch<sup>19</sup> and Ing<sup>20</sup> revealed that the time windows during which stereopsis and fusion develop are during years 1 and 2 of life, respectively. This binocular function timeline favors early surgical correction. Some studies suggested that surgical correction by age 1 year is more effective than that performed later.<sup>21,22</sup> Some even suggested very early surgical correction (at the age of 2–4 months) to develop better binocularity.<sup>14,23</sup> However, this is typically unrealistic because most patients are not presented this early to a strabismus specialist.

Advocates of surgery after age 2 years are concerned about the later development of inferior oblique muscle overaction and DVD, which require separate surgical procedures, and the difficulty of measuring acuity in children who have aligned visual axes. They are unconvinced about the benefits of the monofixation syndrome (peripheral fusion without central fusion). Given the reproducible strabismus measurements, informed and supportive parents, the availability of safer pediatric anesthesia, and the absence of amblyopia, most strabismus surgeons in the United States opt for attempts to achieve horizontal alignment during the patient’s first year of life.

Most ophthalmologists in the United States will choose symmetrical medial rectus muscle recessions on both eyes (possibly adding a monocular or binocular lateral rectus muscle resection or plication for very large deviations). However, monocular surgery is often preferred when one eye has poor vision to avoid the risk of surgical complication in the good eye. Monocular surgery is typically recession of the medial rectus muscle and resection or plication of the ipsilateral lateral rectus muscle. Some surgeons prefer a limbal incision because of the ease of access and orientation as well as the ability to recede contracted conjunctiva and to thus augment the effect of the medial rectus muscle recession. Many prefer the fornix approach popularized by Parks because it avoids proximity to the cornea and results in rapid patient mobilization. It also may have better early cosmesis. Some surgeons prefer to perform recessions measured from the limbus, rather than the original muscle insertion, because of increased

TABLE 11.6.1 Surgery for Infantile Esotropia<sup>a</sup>

Deviation* (Δ)	Symmetrical	Asymmetrical (One Eye)	
	Recess Medial Rectus, Both Eyes (mm)	Resect Lateral Rectus (mm)	Recess Medial Rectus (mm)
30	4.5	5.5	4.5
35	5.0	6.0	5.0
40	5.5	6.5	5.5
50	6.0	7.0	6.0
60	6.5	7.5	6.5
70	7.0	8.0	7.0

\*There are many surgical dosage tables. This one is commonly used around the world.

uniformity. A common protocol for surgical treatment is given in Table 11.6.1. Some variability occurs in certain patient populations. Recently, Park and Oh found that in preterm infants with infantile esotropia, the overcorrection rate was greater than in full-term children, even though the extent of surgery was reduced by 0.5 mm per muscle in preterm patients.<sup>24</sup>

A novel approach to infantile esotropia is the use of botulinum toxin, originally popularized by Scott.<sup>25</sup> In a retrospective study comparing botulinum toxin to surgical bilateral medial rectus muscle recession for esotropia in patients younger than 2 years of age, no statistically significant difference existed in terms of alignment and stereopsis between the groups.<sup>26</sup> Advocates of botulinum toxin argue that reduced anesthesia time gives it a distinct advantage. Many patients, however, require more than a single injection, and because the anesthesia risk primarily occurs during induction and emergence, this advantage may disappear. Potential side effects from the toxin, such as ptosis and the induction of vertical strabismus, are to be considered because these young patients are in the amblyogenic age range.<sup>27</sup>

Patients with DVD usually exhibit no binocularity when DVD is present. The treatment of DVD generally is surgical. The surgery can be symmetrical or asymmetrical and may involve significant recessions of the superior rectus muscles or inferior oblique muscles in the presence of overaction. When there is inferior oblique muscle over action, the most common inferior oblique muscle weakening procedures are myectomy and recession. In mild cases, some recommend a “z” myotomy.<sup>28</sup> Anteriorization of the oblique muscle insertion into the margin of the inferior rectus muscle significantly weakens the muscle and may be an effective treatment for simultaneous DVD. Clear separation between DVD and inferior oblique muscle overaction is necessary, however, because weakening of a normally functioning inferior oblique muscle may cause limitation of elevation in adduction, compensatory head postures, and all the signs and symptoms of cyclovertical muscle palsy.

Course and Outcome

Children who have surgery for infantile esotropia require long-term follow-up because of the possible development of DVD, inferior oblique muscle overaction, FMN, and amblyopia. An optimal result is alignment within 8Δ of orthophoria. Residual esotropia of greater than 10Δ found 4–6 weeks after initial surgery may respond to antiaccommodative measures if the patient has significant hyperopia, with a repeat strengthening procedure likely necessary. This might consist of bilateral lateral rectus muscle strengthening procedure for those who initially underwent bilateral medial rectus muscle recessions, and a recess-resect/plication procedure on the unoperated eye for those who underwent a unilateral procedure. A surgical correction for DVD or inferior oblique muscle overaction may be indicated as well. Thus, it is not uncommon for a patient with infantile esotropia to undergo two to three surgical procedures during childhood. A significant fraction of patients who initially achieve alignment later develop accommodative esotropia and require treatment with glasses.<sup>29</sup> Preoperative parental education regarding these common postoperative scenarios cannot be overemphasized. Asymmetrical monocular pursuit as measured by OKN testing persists indefinitely and may be a perpetual marker for infantile esotropia.

ACCOMMODATIVE ESOTROPIA

Introduction

Accommodative esotropia is the most common esodeviation in children and is characterized by two mechanisms simultaneously occurring in the

same individual. The first mechanism is high hyperopia, with an average of +4.50 D, and the second is a tendency for larger esodeviation at near fixation. This mechanism is called a *high AC/A ratio* and will be discussed in further detail later.

## Epidemiology and Pathogenesis

Accommodative esotropia is characterized by an intermittent esotropia that appears at age 2–3 years; however, earlier onset is not rare. Parents usually note it toward the end of the day or when the child is very tired, ill, or daydreaming (especially at near fixation distances, e.g., across the dinner table). At onset, the child may experience asthenopia as fusional divergence amplitudes are stressed and may rub the eyes or squint; an older child may complain of headaches or diplopia and close one eye. As the esotropia becomes more frequent, abnormal retinal correspondence and suppression, when extant, relieve asthenopic symptoms at the possible expense of fusional divergence amplitudes. Some children maintain intermittent esotropia for long periods, whereas in others the condition degrades quickly to constant esotropia, especially at near fixation, leading to a risk of development of strabismic amblyopia.

## Ocular Manifestations

Patients who have high hyperopia must generate a large, accommodative effort to see clearly at distance and an even larger effort for clear vision at near. They may “choose” blurred vision and straight eyes to maintain comfortable single binocular vision (but at the risk of developing bilateral ametropic amblyopia if high hyperopia is present). Alternatively, they may “choose” clear vision and risk asthenopia and esotropia. Those patients who have high hyperopia, but do not develop esotropia and maintain excellent acuity, often have low AC/A ratios.

Patients with high AC/A ratios have greater deviation at near because of overactive convergence response to a given accommodation requirement. This ratio can be calculated by using two methods—the *heterophoria* method and the *gradient* method—as described in [Box 11.6.3](#). A ratio up to 6/1 is considered normal. An accurate calculation of the AC/A ratio generally is not required in a clinical setting, and some have suggested treating the AC/A ratio as a concept, rather than a quantity.<sup>5</sup> The rule of thumb is if the esotropia at near is greater than the esotropia at distance by 10Δ or more, a high AC/A ratio exists. Patients who have low hyperopia or myopia can also have a high AC/A ratio and develop an esodeviation greater at near.

## Diagnosis and Ancillary Testing

Alignment at distance and near, together with upgaze and downgaze (to detect A/V patterns) will provide most of the valuable information for the examiner. In patients who have a V-pattern esotropia with greater deviation in downgaze, it is important to measure near deviations in primary position to avoid confusion with V-pattern esotropes.

The other crucial information is the accurate cycloplegic refraction to determine the full degree of hyperopia. Historically, atropine has been considered essential to obtain the maximal hyperopic refractive error; however, its use requires a return visit (typically after 2–3 days of atropine instillation), its cycloplegic effect is prolonged and may be associated with systemic side effects. Nowadays, the standard cycloplegic agent is cyclopentolate with or without tropicamide. It permits short onset and, in most patients, provides results within +0.50 D of the refractive error obtained using atropine. Children with dark irides might have residual esotropia because of latent uncorrected hyperopia, and atropine refraction should be considered to uncover the full hyperopic refraction.

If the esodeviation cannot be found on initial attempts, occlusion of one eye for 45 minutes to 3 hours may be carried out, or cycloplegia can be induced and cover testing performed by using suitably large targets. An esodeviation after cycloplegia provides strong confirmation of parental observations and may be sufficient to warrant initiation of treatment.

## Differential Diagnosis

Infrequently, a child presents with sudden diplopia and comitant esotropia—acute acquired comitant esotropia (AACE). Although many cases are nonneurological, comitance does not rule out the possibility of an underlying neurological condition, such as intracranial tumors, Chiari malformation, and hydrocephalus. In a recent series of 48 children with AACE, 6% had intracranial disease. Imaging may be warranted, especially

### BOX 11.6.3 Accommodative Convergence-to-Accommodation Ratio Calculations

#### Heterophoria Method

Determine the distance and near deviation in prism diopters and the interpupillary distance in centimeters.

$$AC/A = IPD(\text{cm}) + \frac{(\Delta_2 - \Delta_1)}{F}$$

where

AC/A ≡ accommodative convergence to accommodation

IPD ≡ interpupillary distance

Δ<sub>1</sub> ≡ distance deviation (eso is +, exo is −)

Δ<sub>2</sub> ≡ near deviation

F ≡ near fixation distance in diopters of accommodation (1/2 meter ≡ 2 D, 1/3 meter ≡ 3 D)

#### Example

IPD ≡ 60 mm or 6 cm

Δ<sub>1</sub> ≡ 3 ET

Δ<sub>2</sub> ≡ 30 ET

F ≡ 1/3 m ≡ 3 D

$$AC/A = 6 + \frac{30 - 3}{3} = 15 \text{ (high)}$$

#### Gradient Method

Determine eye deviation in prism diopters at a fixed distance with and without a supplemental lens correction (generally +3 D lens).

$$AC/A = \frac{\Delta_1 - \Delta_2}{D}$$

Δ<sub>1</sub> ≡ ocular deviation without lens

Δ<sub>2</sub> ≡ ocular deviation with lens

D ≡ power of lens used

#### Example

Δ<sub>1</sub> ≡ 25 ET

Δ<sub>2</sub> ≡ 16 ET

D ≡ +3.00

$$AC/A = \frac{25 - 16}{3} = 3 \text{ (normal)}$$

in the setting of greater deviation at distance than near, age greater than 6 years at presentation, recurrent AACE, or other neurological signs.<sup>30</sup> Other entities are listed in [Box 11.6.2](#).

## Treatment, Course, and Outcome

Treatment consists of antiaccommodative measures, primarily the prescription of most or all of the patient's hyperopic refractive error (to do the focusing for the child so accommodation and thus convergence are not stimulated) ([Fig. 11.6.6](#)). Parents must be warned that once glasses are prescribed, the child may exhibit larger and more frequent esodeviations when glasses are removed.

The fit of eyeglasses for infants and toddlers is challenging because of the frame weight, flat nasal bridge, lack of cooperation, and small face but is imperative for adequate treatment. The child is re-evaluated after a month's full-time wear of the prescription. If the distance and near esodeviations are reduced to within the monofixational range (≤8Δ of esotropia) and the child has a comfortably controlled phoria and no asthenopic signs or symptoms, the treatment is considered initially successful and the patient is re-evaluated 3–6 months later, depending on age. Assessment of visual acuity at distance and near, assessment of alignment at distance and near, and sensory testing are monitored. Cycloplegic refractions are repeated periodically. If the distance tropia is greater than the above limit, the cycloplegic refraction is repeated. If the greater deviation persists despite full hyperopic prescription, the patient becomes a candidate for surgery. If the distance deviation is controlled but an esotropia greater than the above limit is present at near fixation, or if a symptomatic phoria at near fixation persists, the patient can be given bifocal glasses.

The height of the bifocal segment needs to be high enough to split the pupil in primary position to be functional in young children. The initial bifocal strength may be estimated from measurement of the near esodeviation by using various strengths of trial frame lenses or arbitrarily given as

**Figure 11.6.6 Accommodative Esotropia.** (A) Without hyperopic correction there is prominent right esotropia. (B) Eyes are straight with full hyperopic correction. This patient is dilated in the left eye from amblyopia penalization treatment of the better seeing left eye.

+2.50–3.00 D. The patient is asked to wear the bifocals with re-evaluation to be done in 1–2 months. One study found that despite their widespread use, bifocals did not improve the outcomes in children with accommodative esotropia with high AC/A.<sup>31</sup>

When the successfully treated child is about 5 years of age, the parents may note less esodeviation without glasses; at about 6 years of age, the power of the glasses often can be weakened progressively, roughly 0.50–0.75 D every 6 months, beginning with the bifocals. A common practice is to place the weaker correction in a trial frame and perform cover testing; occasionally, a patient appears to have alignment during this office evaluation but develops significant esodeviation, asthenopic symptoms, or both, when the weaker correction is worn. In such cases, the patient should return to the previous stronger prescription. It often is possible to eliminate bifocals by age 8 or 9 years and the mild to moderate hyperopic correction by the early teenage years. Patients who have high hyperopia, significant astigmatism, or anisometropia may require optical correction for acuity purposes after their accommodative esotropia has resolved, and this can sometimes be done with contact lenses.

Patients whose treatment is initiated after age 4 years may not accept their full hyperopic correction without a period of cycloplegia (e.g., one drop of atropine in both eyes). Ideally, the minimal correction necessary to provide and maintain comfortable single binocular vision and (in the case of high hyperopia) good visual acuity is prescribed. After age 6 years, the AC/A ratio tends to normalize, but hyperopia may increase. Rarely, treatment of accommodative esotropia with miotics, such as ecthiopate iodide 0.125%, may be indicated. This cholinesterase inhibitor causes pharmacological accommodation (and miosis), which results in reduction of the accommodative effort and, therefore, less associated convergence. The ideal candidate for this treatment would be a patient with high AC/A ratio; or it can be used as a temporary measure in older children when wearing glasses is not desired, such as during sports or social events. V-pattern esotropia with the greatest deviation in downgaze is another condition

where miotics can be employed. One of the most common side effects are iris cysts along the pupillary margin; these cysts typically regress when the drop is discontinued or when topical 2.5% phenylephrine is added. Other notable side effects include brow ache and prolongation of respiratory paralysis in patients undergoing general anesthesia with succinylcholine. Miotics are less popular now, partly because it is difficult to obtain in the United States.

At any time after a period of successful antiaccommodative treatment, a patient may develop esotropia that cannot be controlled with glasses.<sup>32</sup> Repeat refraction is carried out, and if greater hyperopia is found, the full hyperopic correction is prescribed. It is difficult to predict the effect of even as little as +0.50 D additional correction on a decompensated accommodative esotrope. If no effect is obtained after a few weeks' trial, the patient is said to have partially accommodative esotropia and should undergo strabismus surgery.

For most ophthalmologists, bimedial recession classically directed toward the nonaccommodative component of the esodeviation is the procedure of choice. The target angle, however, is debatable and includes correcting for the residual deviation at distance and at near or the average deviation between distance and near. Some surgeons empirically add 1 mm recession per medial rectus muscle for a high AC/A ratio. Others believe that posterior fixation sutures combined with medial rectus muscle recessions benefit patients with high AC/A ratios.<sup>33</sup> In general, patients with high AC/A ratios are more difficult to manage.<sup>34</sup> Some utilize the prism adaptation test to reduce the underresponse rate—that is, prescribing base-out prisms for the residual esotropia over the full hyperopic correction until no esotropia is present and operating for that angle.<sup>35</sup> Parents must be warned about the continual need for antiaccommodative treatment even after strabismus surgery, which typically consists of eyeglasses. Hyperopic laser in situ keratomileusis (LASIK) has been effective mainly in older patients (ages 10–52 years)<sup>36</sup> but is not commonly used for accommodative esotropia in the United States for many reasons, including the usual shift toward emmetropization over time. Studies have shown that around 60% of children can be weaned out of spectacles during their grade school years.<sup>37,38</sup>

A difficult group of patients consists of teenagers who have their condition well controlled with bifocals or high hyperopic correction but who have aesthetic concerns. A switch to contact lenses places less accommodative demand on the patient and may enable comfortable single binocular vision at near fixation without the need for separate reading glasses. Bifocal contact lenses may be tolerable to some patients; few are satisfied with “monovision” fitting of one lens for distance and another for near. Progressive bifocals may be tolerated by some teenagers and permit persistent bifocal treatment without the dysaesthetic impact of a bifocal line. Finally, cautious single medial rectus muscle recession or small bimedial rectus muscle recession may be performed in those patients who fuse at distance when wearing single-vision lenses and who wish to be rid of their bifocals.

The effective management of accommodative esotropia demands a long period of cooperation among patient, physician, and parents and is as much art as science. Nowhere else in strabismus management are communication skills more important than in the management of accommodative esotropia.

## CYCLIC ESOTROPIA

This rare form of strabismus, first reported by Burian<sup>39</sup> in 1958, is a condition of intermittent esotropia most commonly presenting as alternate 12- to 36-hour periods of perfect alignment followed by constant, usually large-angled (30–40Δ) esotropia. The age of onset is generally 3–4 years. When the eyes are aligned, excellent fusional abilities and stereopsis are found; when esotropia is present, patients exhibit abnormal retinal correspondence and suppression. Some patients who have cyclic esotropia display irritability and emotional withdrawal during periods of strabismus. The incidence of cyclic esotropia has been estimated to be 1 in 5000 cases of strabismus. Aids to diagnosis include a strong suspicion and a log of the strabismus periods kept by the parents. This condition differs from early intermittent accommodative esotropia because cycles are strictly repetitive, and during the aligned periods, little or no strabismus may be elicited despite prolonged occlusion.

The cause is unknown but may be related to the “biological clock” phenomenon popularized by Richter.<sup>40</sup> Some patients develop cyclic esotropia after head trauma, a neurosurgical procedure, strabismus surgery, or infection. Most patients eventually decompensate to a constant strabismus and require surgery.

Antiaccommodative measures usually have little effect during periods of strabismus and are not needed during aligned periods. Surgical treatment is successful in 75%–90%<sup>41</sup> of cases in attaining alignment with one operation, whether performed during aligned or strabismic periods.

## MOEBIUS' SEQUENCE

Moebius' sequence consists of unilateral or bilateral facial nerve palsy with abduction limitation. It may be associated with other cranial nerve palsies, orofacial dysmorphism, distal limb or axial malformations, and intellectual impairment.<sup>42,43</sup> Some young infants have difficulty suckling, as well as abnormal phonation. The upper motor neuron seventh cranial nerve palsies cause smooth facies, lagophthalmos, absent nasolabial folds, rounded mouth, and decreased facial emotional responses. In a series of 46 patients with Moebius' sequence, three patterns of ocular motility occurred: (1) orthotropia in primary position with complete abduction and adduction deficits (41%), (2) large-angle esotropia with cross-fixation (50%), and (3) large-angle exotropia with torticollis, absence of convergence, and vertical eye misalignment (9%).<sup>43</sup> Most, if not all, patients lack binocular function. When cross-fixation is present, it is similar to infantile esotropia; as a rule, however, abduction to the midline cannot be performed.<sup>43</sup> Patients who have esotropia generally have tight medial recti on forced duction testing<sup>44</sup>; those who have gaze palsy and straight eyes in primary gaze do not.

The cause of the esotropia may include both involvement of sixth cranial nerve fascicles and nuclei, as well as an aberrant medial rectus muscle insertion because some patients have medial recti that insert quite close to the limbus. No treatment is necessary or highly successful in patients who have gaze palsies alone. Those who have esotropia and are unable to abduct to the midline require medial rectus muscle recessions. These recessions may be technically quite challenging because the muscles are very tight and difficult to hook, suture, and safely detach from the globe. Double-overlapping marginal myotomies may be safer in some situations. Resections of the nonfunctioning lateral recti are avoided, as they are generally ineffective.

## DUANE'S SYNDROME

### Epidemiology and Pathogenesis

Duane's syndrome, or Duane's retraction syndrome, which accounts for 1% of all strabismus, is a congenital, usually sporadic miswiring of the medial and lateral rectus muscles, resulting in abnormal horizontal eye movements. The most common variant of this syndrome is Duane type 1 (85%) being more common in girls (60%) and affecting the left eye (60%). It is characterized by limited abduction of the involved eye and often has a "tether" phenomenon, which consists of overelevation or overdepression on attempted adduction as the retracted globe escapes from its horizontal rectus muscle restrictions<sup>45</sup> (Fig. 11.6.7). This specific pattern can distinguish between Duane's syndrome and sixth cranial nerve palsy.

### Ocular Manifestations

Neuropathologically, this disorder has been shown to be caused by an absent sixth cranial nerve nucleus and nerve and innervation of the lateral rectus muscle by a branch from the inferior division of the third cranial nerve.<sup>46,47</sup> Thus, classic electromyographic findings of absent lateral rectus muscle firing upon attempted abduction, and firing of both horizontal recti upon attempted adduction, are explained.<sup>48</sup> Simultaneous contraction

of both muscles will cause globe retraction and decreased palpebral fissure on adduction. No mechanism exists to improve the abduction limitation. Typically, patients who develop esotropia and tight medial rectus muscles adopt a head turn toward the affected eye (e.g., a left head turn in a left type I Duane) to maintain single binocular vision (Fig. 11.6.8), or they maintain a straight head but accept esotropia, abnormal retinal correspondence, and suppression, if extant. In general, since these patients develop an abnormal head posture to maintain binocularity, amblyopia is uncommon.

Duane's syndrome is bilateral in roughly 20% of cases; less common forms include type II (14%), with limitation of abduction and a tendency toward exotropia, and type III (1%), with limitation of both abduction and adduction and any form of horizontal strabismus.

### Treatment

The indications for surgical correction are chronic abnormal head posture, manifest deviation in primary position, significant upshoots or downshoots and disfiguring globe retraction. The amount of esotropia in monocular Duane's syndrome type I is rarely greater than 30Δ. The examiner should make sure that alignment in primary position is measured without any head turn, otherwise esotropia will be underestimated. Recession of the ipsilateral medial rectus muscle aligns the eye but does not improve abduction beyond primary position. Rarely, very large weakening procedures on the medial rectus muscle result in consecutive exotropia, but the mechanisms are unclear. A small medial rectus muscle recession in the opposite eye can help stabilize the pathological eye in primary position by application of Hering's law.<sup>49,50</sup> Resection of the lateral rectus muscle generally is avoided, as it increases retraction and may not improve abduction. Various surgical options of lateral transposition of the vertical rectus muscles has been shown to improve abduction of the affected eye.<sup>51,52</sup>

The tether phenomenon may be improved surgically by using posterior fixation sutures for the horizontal rectus muscle or by horizontal splitting of the lateral rectus muscle into a "Y" structure, with resuturing of the muscle above and below the axis of the lateral rectus muscle. If extreme retraction with pseudoptosis is dysaesthetic, both horizontal recti may be recessed to relieve the retraction.

### Systematic Associations

Systemic associations in 30% of cases include: Goldenhar's syndrome (also known as *oculo-auriculo-vertebral syndrome* or *facio-auriculo-vertebral dysplasia*); Klippel-Feil syndrome; a rare autosomal dominant form; the Wildervanck association of Duane's syndrome, and congenital labyrinthine deafness. Brainstem auditory evoked responses occasionally are abnormal, which suggests widespread neurological abnormalities.

## STRABISMUS FIXUS

This rare, congenital, stationary, very large-angle esotropia of unknown cause may represent a form of congenital fibrosis of the medial rectus muscles. The condition differs from strabismus fixus seen in adults, which typically occurs in the presence of high myopia ("heavy eye syndrome," discussed later in this chapter). Usually, no abduction is possible, and strabismus surgery on these very tight muscles often is of little benefit.

**Fig. 11.6.7 Versions in Duane's Syndrome Type I.** This child has Duane's syndrome type I in his left eye. (A) Very mild esotropia in primary gaze. (B) On left gaze (direction of arrow), there is no abduction of the left eye beyond the midline. Lid fissure widens on attempted abduction. (C) On right gaze (direction of arrow), the lid fissure of the left eye narrows, and the globe displays an upshoot on attempted adduction of the left eye.

**Fig. 11.6.8 Head Posture in Left Duane's Syndrome Type I.** This child has a face turn to the left to compensate for deficient abduction in the left eye. London, New York: Gower Medical Publishing; 1984. p. 6.7.)

## ESOTROPIA IN THE NEUROLOGICALLY IMPAIRED

The incidence of strabismus is higher in the population of neurologically impaired children than in the general population. In addition to the previously mentioned categories, children with neurological impairment may have a variable intermittent esotropia that is unresponsive to antiaccommodative measures; it may be stable, worsen to a constant tropia, or disappear with maturity. Surgery is avoided unless measurements of the deviation are reproducible, the patient is intellectually capable of benefiting from improved binocular function, and the effects of any neurotropic medications, especially sedatives, are considered. Surgical outcome may be less successful in these patients, but antiaccommodative measures may be helpful.<sup>53</sup> The population of patients with Down syndrome with strabismus are an exception and appear to respond better than most groups of children with neurological impairment.<sup>54</sup> In addition, a patient under significant emotional stress occasionally presents with temporary esotropia, sometimes related to accommodative spasm. Transient esotropia and diplopia during vigorous exercise also have been reported,<sup>55</sup> but the mechanism is poorly understood.

## ESOTROPIA ASSOCIATED WITH VISUAL DEFICIT (SENSORY ESOTROPIA)

Children who have impaired vision in one or both eyes are at risk for the development of strabismus. Esotropia develops in a high proportion of infants younger than age 2 years who have decreased acuity secondary to congenital cataract, corneal opacity, retinal pathology, or other devastating media clarity impairment. Early surgery for media diseases has a low prognosis for the development of stable single binocular vision. In cases of unilateral blindness and esotropia, the surgical approach often is best limited to the involved eye. Strabismus surgery outcomes in this population are guarded and likely correlate with the poor fusion and the dense amblyopia associated with this condition.<sup>56</sup>

## THE “HEAVY EYE SYNDROME” AND THE “SAGGING EYE SYNDROME”

In some patients who have acquired esotropia with high myopia, the lateral rectus muscle shifts inferiorly and the superior rectus muscle shifts nasally, leading to esotropia and hypotropia.<sup>57</sup>

A different group of patients with acquired esotropia have divergence insufficiency or divergence paralysis esotropia. These older patients do not have high myopia. They have comitant esotropia and diplopia at distance fixation and fusion at near fixation with minimal abduction deficit.<sup>58</sup> Orbital imaging studies of these patients have shown degeneration of the lateral rectus–superior rectus band, which results in an inferior displacement of the lateral rectus muscle. Therefore, the term “sagging eye syndrome” has been suggested for the condition in this group of patients.<sup>59</sup> Both medial rectus recession and lateral rectus resection/plication are effective surgical options.<sup>58,60</sup>

# Exotropia

Daniel J. Salchow

# 11.7

**Definition:** Divergent misalignment (outward deviation) of the visual axes of the eyes, which may manifest constantly or intermittently. It may be acquired or congenital, most often its etiology is unknown (primary forms of exotropia) but may be secondary to other underlying causes.

## Key Feature

- Outward deviation of one eye.

## Associated Features

- History of closing one eye in bright sunlight (intermittent exotropia).
- Amblyopia, if present, usually mild unless exotropia constant.
- Inferior or superior oblique muscle overaction may be present.
- A, V, or other “alphabet” patterns in some cases.

## INTRODUCTION

Exotropia is a manifest divergent misalignment of the visual axes of the eyes. A latent outward deviation is called *exophoria*.

Intermittent exotropia (IXT; Fig. 11.7.1) is the most frequent cause of exotropia. It is a primary exotropia, and its cause remains unknown. In many patients, IXT may be considered a progressive disease; an exophoria may decompensate to an intermittent exotropia and finally to a constant exotropia.<sup>1,2</sup> Von Noorden reported that in 75% of patients, the condition progressed, in 9%, it did not progress, and in 16%, it improved with time.<sup>2</sup>

**Fig. 11.7.1 Intermittent Exotropia.** (A) Eyes straight. (B) A few moments later, the exotropia has become manifest. (Courtesy Howard Eggers.)

This highlights the need for regular observation, particularly in children with IXT.

Infantile exotropia, another primary exotropia, is very rare.<sup>3</sup> It presents with constant exotropia in the first 6 months of life.

Exotropia also may be secondary to oculomotor palsy, Duane's syndrome, craniofacial disorders, internuclear ophthalmoplegia (INO), and other disorders. Sometimes an exotropia develops after surgery for esotropia, which is termed *consecutive exotropia*, or it even develops spontaneously in patients who had infantile esotropia. The distinction between primary and secondary exotropia usually is straightforward because of characteristic findings in cases of secondary exotropia. Sensory exotropia denotes an exotropic eye with severely reduced vision.

## EPIDEMIOLOGY AND PATHOGENESIS OF INTERMITTENT EXOTROPIA

IXT makes up about 50% of exotropias in children<sup>4</sup>; its incidence in the United States is 32.1 per 100 000 in persons under 18 years.<sup>5</sup> IXT is more common in Asian populations<sup>6–10</sup> and possibly also in women.<sup>10–12</sup> Patients with IXT may more frequently develop other disorders, such as attention deficit hyperactivity disorder (ADHD) and adjustment disorder.<sup>13</sup> The distribution of refractive errors in patients with IXT is similar to that in the general population.<sup>14</sup> A positive family history increases the risk for exotropia. Inheritance is probably polygenetic.<sup>15,16</sup>

## OCULAR MANIFESTATIONS OF INTERMITTENT EXOTROPIA

IXT typically presents between ages of 2 and 4 years with a gradual onset of exodeviation, more frequently noted when the child fixes on a distant target. Squinting (closing) of the deviating eye and eye rubbing in bright sunlight are noted frequently and may be the presenting complaint. Contracture of lateral recti in long-standing cases of constant exotropia, true overaction of oblique muscles, lateral gaze incomitance, and alphabet patterns may be associated. In many patients with IXT, normal retinal correspondence is present when their eyes are aligned and anomalous retinal correspondence when the eyes deviate; these patients rarely complain of diplopia.<sup>17</sup> When the deviation has been latent for a long time, these sensory adaptations may not develop, and these patients experience diplopia when they have exotropia. The angle of the deviation often is stable until secondary contracture of the lateral recti ensues.

## Classification of Intermittent Exotropia According to Distance/Near Angle

In basic-type IXT, the difference between the distance and near angles is 10 prism diopters (PD) or less. In divergence excess type IXT, the distance angle exceeds the near angle by greater than 10 PD, in convergence insufficiency-type IXT, the near angle exceeds the distance angle by greater than 10 PD.<sup>18</sup> Diagnostic monocular occlusion ( $\geq 1$  hour) may be helpful, particularly in divergence excess-type IXT, which may convert to basic-type IXT. After diagnostic occlusion, if the distance angle still exceeds the near angle by more than 10 PD, the accommodative convergence-to-accommodation (AC/A) ratio should be determined by using the gradient method. If the exotropia at distance decreases by more than 12 PD when  $-2$  D lenses are placed before both eyes, the AC/A ratio is increased. Patients with divergence excess-type IXT and increased AC/A ratio are at risk for

TABLE 11.7.1 “Office Control Score” to Assess Control of Intermittent Exotropia<sup>18</sup>

5	Constant exotropia
4	Exotropia manifests >50% before dissociation
3	Exotropia manifests <50% before dissociation
2	Exotropia manifests only after dissociation, fusion in >5 seconds
1	Exotropia manifests only after dissociation, fusion in 1–5 seconds
0	Exotropia manifests after dissociation, fusion in <1 seconds (phoria)

Note: The examiner takes the score for distance and near fixation and uses the average. The higher the score, the poorer the control.

postoperative overcorrection (esotropia) at near and may require bifocal spectacles postoperatively, and this should be discussed before surgery.

Control of Intermittent Exotropia

Patients with IXT are able to intermittently align their eyes (control of IXT). If control is poor and exotropia manifests frequently, the risk for visual complications increases. Although often subjectively judged by the examiner (“good” – “fair” – “poor”) control can be assessed in standardized ways by using “control scores” (Table 11.7.1<sup>19</sup> and Table 11.7.2<sup>20</sup>). Since control may be variable, these scores also can vary even during one examination.<sup>21</sup>

Complications of Exotropia

Amblyopia occurs in 3%–4.5% of children with IXT.<sup>4,22</sup> Loss of binocular function (stereopsis) may complicate IXT, especially in children, particularly if phases of manifest exotropia increase. Generally, the better the control, the lower is the risk for these complications.

Contracture of the lateral recti may occur in patients with long-standing IXT and in those with constant exotropia. Adduction may be limited, and the tight lateral recti may act as tethering cords. On attempted elevation and depression in adduction, the globe may overelevator or overdepress, and this may be confused with oblique muscle dysfunction. However, both the inferior oblique and superior oblique muscles rarely may become truly overactive in patients with IXT. Forced duction testing of the oblique muscles differentiates those with true oblique muscle overaction from those with merely tight lateral recti.<sup>23</sup>

Some patients with IXT have less misalignment on side-gaze than in the primary position and have been considered at greater risk for surgical overcorrection.<sup>24</sup> Many patients have greater deviations in upgaze, downgaze, or both, than in the primary position; some have oblique overaction,

BOX 11.7.1 Differential Diagnosis of Exotropia

- Pseudo-exotropia from large, positive angle  $\kappa$  or hypertelorism
- Intermittent exotropia
- Decompensated exophoria
- Third cranial nerve palsy with medial rectus weakness
- Duane’s syndrome type II
- Synergistic divergence
- Infantile exotropia
- Exotropia in craniofacial syndromes (secondary to orbital anomalies)
- Convergence insufficiency/paralysis (e.g., in Parkinson’s disease)
- Exotropia consecutive to surgery for esotropia

which may explain the incomitance. All “alphabet patterns” may be found, from the common A (greatest deviation in downgaze) and V (greatest deviation in upgaze) patterns to the X, Y, and  $\lambda$  patterns discussed in depth in Chapter 11.8.

DIAGNOSIS AND ANCILLARY TESTING FOR EXOTROPIA

A family history of strabismus should be sought, as well as an estimation of age of onset, progression in frequency and severity, and recognition by family, friends, and teachers. Previous treatment for strabismus should be noted.

The ophthalmologist should study the alignment of the eyes as the patient enters the room and during the medical history to gain insight into the alignment under ordinary viewing conditions. Sensory tests for the presence of anomalous retinal correspondence, suppression, and stereopsis are performed first and evaluated, as discussed in Chapters 11.4 and 11.5, followed by the assessment of control in patients with IXT.

The cover test is used to detect exotropia, and the uncover test and alternate cover test are used to detect exophoria. The angle should be measured with the alternate cover test and prism test by using an accommodation-controlling target in the primary position at distance (ideally 20 ft [6 m]) and at near (1 ft [0.3 m]) fixation and in gazes right, left, up, and down at distance fixation. Ductions and versions are evaluated to search for oblique muscle dysfunction or contracture of the lateral recti. Evaluation of alignment at far distance fixation (horizon seen through a window or at the end of a long hallway) may uncover larger angles by minimizing the influence of accommodative convergence.

Sometimes, parents of children with IXT note strabismus at home, but the physician cannot detect misalignment with typical cover tests. Diagnostic occlusion may be used to disrupt fusion, and the eye is uncovered at the moment of alternate cover testing.

DIFFERENTIAL DIAGNOSIS

Only rarely is IXT confused with another form of strabismus; should it decompensate to constant exotropia, it must be differentiated from infantile exotropia and exotropia associated with other entities (Box 11.7.1). Inferior oblique muscle overaction and dissociated vertical deviation are common in infantile exotropia, but latent nystagmus is rare. Spontaneous alignment sometimes occurs by age 1 year; surgical correction by age 2 years provides alignment with monofixation syndrome as a satisfactory outcome in most cases.<sup>25</sup>

TREATMENT

Correction of Refractive Errors

Successful treatment of intermittent exotropia requires correction of any significant refractive error. Myopia is corrected fully to improve visual acuity at distance and to stimulate accommodative convergence. Significant hyperopia (greater than +3.00 D) is partially corrected as well because uncorrected high hyperopia may be associated with hypoaccommodation and poorer control of IXT.<sup>26</sup> Treatment of amblyopia alone rarely improves alignment, but treatment compliance before surgery is often better, and it is easier to follow visual acuity levels in each eye in nonverbal children before the eyes are aligned.

### BOX 11.7.2 Features Considered in the Decision on Surgical Treatment

Increasing frequency of strabismus (manifest 50% of the time or more)  
Decreasing binocularity (e.g., stereopsis)  
Decompensation from intermittent to constant exotropia  
Increasing symptoms of squinting and rubbing of eye(s), asthenopia, accommodative spasm  
Strabismus noted by friends, teachers, strangers  
Cosmetic deformity if obvious manifest deviation

## Orthoptic Treatment

Orthoptic training is based on the concept of deficient motor fusion and has been performed in some fashion for more than 80 years. Fusional vergence amplitudes may be enhanced, when deficient, by using a major amblyoscope or fusional training exercises in free space. Other techniques utilize monocular targets or stereograms.<sup>27</sup> Results vary, depending on the success criteria; long-term results, however, are lacking.

## Therapeutic Occlusion

Part-time monocular occlusion (alternating if amblyopia is absent) may improve control of IXT in some. Evidence of its long-term effectivity in the treatment of IXT is lacking.<sup>28</sup> It is sometimes used as a measure to delay strabismus surgery.

## Overcorrecting Minus Lenses

Overcorrecting minus lenses (−2.00 to −4.00 D over the habitual distance prescription) can stimulate accommodative convergence and may improve fusional control of IXT. The angle of the deviation decreases and control improves in most IXT patients in response to overcorrecting minus lenses.<sup>29–31</sup> These lenses usually are reserved for children because children have a larger accommodative reserve. Adverse effects include asthenopic complaints (eye strain, headache). Randomized trials on this topic are lacking.

## Optical Treatment

Use of therapeutic (base-in) prisms has been attempted in some patients with IXT, with questionable long-term efficacy. Typically, about 50% of the maximal distance deviation is corrected with prisms. In most younger patients, fusional convergence is relaxed in response to the prism (“eat” the prism), and the physician has to increase the prism strength progressively; older patients who have more constant exotropia and limited fusional amplitudes may respond more positively. IXT may become more constant when the prism glasses are removed. Prisms greater than 10 PD are difficult to incorporate into lenses; thus, Fresnel membrane prisms are more useful for larger deviations, although they cause a blurring effect (see Chapter 11.12).

## Pharmacological Treatment

By injecting pharmacological agents, extraocular muscles can be strengthened or weakened. Botulinum toxin weakens a muscle, and injection of 2.5 IU into both lateral recti can reduce the angle from 30 PD to 6–10 PD in children. The success rate after 6 months ranges from 40% to 70%; retreatments are frequently required (37.5%).<sup>32,33</sup> Adverse effects include upper lid ptosis and persistent consecutive esotropia.

To strengthen an extraocular muscle, bupivacaine (a calcium channel blocker) may be injected. Preliminary reports have shown encouraging results.<sup>34</sup>

## Surgical Treatment

Strabismus surgery is appropriate after conservative approaches have been attempted without satisfactory results. Patients with IXT become reasonable surgical candidates when many of the features listed in Box 11.7.2 are present. Patients with exotropia under 10Δ associated with the monofixation syndrome do not usually benefit from surgery unless a symptomatic latent component is present.

Children operated before age 7 years, and those in whom the deviation is present for less than 5 years may have better surgical results.<sup>35</sup> However,

TABLE 11.7.3 Advantages and Disadvantages of Bilateral and Unilateral Surgery for Exotropia

	Advantages	Disadvantages
Bilateral surgery (recession of both lateral recti or resection/plication of both medial recti)	Does not create lid fissure anomalies on side-gaze Recessions do not sacrifice muscle tissue Does not alter refractive error	Bilateral surgery may be difficult to explain to patients who note monocular strabismus Monocular surgery lends itself more readily to local anesthesia techniques
Unilateral surgery (recession of one lateral rectus and resection/plication of one medial rectus)	Preferred if one eye deeply amblyopic Preferred if patient demands surgery on one eye Monocular surgery lends itself more easily to local anesthetic techniques	Resections/plications involve disposal of muscle tissue Often leads to subtle lid tissue anomalies on side-gaze (wider in abduction than adduction)

TABLE 11.7.4 Suggested Extent of Surgery for Patients With Exotropia

Deviation (Δ)	Recess Lateral Rectus by (mm)	Resect Medial Rectus by (mm)
12	3.5	2.5
15	4.0	3.0
20	5.0	4.0
25	6.0	5.0
30	7.0	6.0
35	7.5	7.0
40	8.0	8.0
45	8.5	9.0
50	9.0	10.0
60	10.0	
70	11.0	

The amounts require the suture to be placed 1.0–1.5 mm from the lateral rectus insertion. Adapted from data from Marshall M. Parks, MD.

timing of surgery is an individual decision and should take into account the patient's (and parents') needs and wishes.

The surgeon must decide between bilateral surgery (bilateral lateral rectus muscle recession or bilateral medial rectus muscle resection or plication) and unilateral surgery (recession of one lateral rectus muscle combined with resection or plication of the ipsilateral medial rectus muscle). Historically, bilateral lateral rectus muscle recession was reserved for patients with divergence excess type IXT. Patients with convergence insufficiency type IXT received resection or plication of both medial recti, all others received unilateral surgery. The question whether unilateral or bilateral surgery yields better results has not been settled; both are effective. The advantages and disadvantages of bilateral and unilateral surgery are listed in Table 11.7.3. For exotropias larger than 40–50 PD, more than two muscles should be operated on.

Suggestions for the surgical amounts for given deviations are provided in Table 11.7.4. Most surgeons operate for the maximal deviation at distance fixation except in patients with convergence insufficiency; in those patients, some surgeons operate for the maximal deviation at near fixation, whereas others choose a more cautious approach and only correct the maximal deviation at distance fixation to avoid overcorrection. Patients whose deviation decreases by greater than 10Δ in lateral gaze from primary position should have 1 mm less lateral rectus muscle recession performed on the side of the lesser deviation. All patients should be warned of the possibility of postoperative diplopia.

## COURSE AND OUTCOME

Consecutive esotropia is a complication of surgery for exotropia, but recurrent exotropia is significantly more common. Reconstructive success may be defined as an esotropia or exotropia of less than 15Δ, and functional success is often defined as a small asymptomatic phoria or constant tropia less than 10Δ with peripheral fusion, or small residual intermittent exotropia. Published success rates after one operation are 70%–95% for reconstructive success and 44%–90% for functional success. Patients should be warned of the smaller lateral visual field expanse that occurs after successful surgery, and the potential for pseudo-ptosis as the vertical eyelid fissures may not be artificially widened as they are with large angle exotropias.

# Torsional Strabismus

Scott K. McClatchey, Linda R. Dagi

# 11.8

**Definition:** Strabismus related to ocular torsion.

## Key Features

- A- and V-pattern deviations.
- Oblique overactions and underactions.
- Torsion of the globe.

## INTRODUCTION

### Definitions of Inferior Oblique Overaction, Superior Oblique Overaction, A-Pattern, and V-Pattern

“Oblique muscle overaction” and A- or V-pattern strabismus, are defined on the basis of clinical examination findings. Inferior oblique overaction (IO OA) is an elevation of the adducting eye in side gaze, whereas superior oblique overaction (SO OA) is a depression of the adducting eye in side gaze. In the extreme limits of gaze, the adducting eye may demonstrate exodeviation as well as a hypertropia (IO OA) or hypotropia (SO OA). The term “overaction” implies hypertonicity or excess neural stimulation; this clinical appearance, however, does not necessarily mean the oblique muscles are truly overacting. Instead, the term “oblique overaction” is used because the oblique muscles have their greatest vertical action when the eye is adducted. A common system for grading oblique overaction is 0 (normal) to 4+ (extreme).

A- and V-patterns are defined by the difference in horizontal deviation in upgaze compared with downgaze, where the patient is fixing on an

accommodative distance target, and the vertical gaze angle is about 30° from the primary gaze:

- A-pattern—at least 10 prism diopter (PD) lesser exodeviation or greater esodeviation in gaze up than down (Fig. 11.8.1).
- V-pattern—at least 15 PD greater exodeviation or lesser esodeviation in upgaze than downgaze (Fig. 11.8.2).

Precise head positioning when measuring deviation in side-gaze or up- or downgaze is difficult,<sup>1</sup> especially in children. Thus, the incomitant deviation in up- and downgaze may vary inadvertently, depending on the variable direction of gaze. Because of this, many clinicians simply label A- and V-patterns as mild, moderate, or large.

### The Three Axes of Strabismus

To understand these types of strabismus, it is important to understand the three axes of ocular motion. Each globe has 3° of freedom, and thus the motions of the eye fall into three orthogonal axes: horizontal, vertical, and torsional. Misalignment in the horizontal axis is seen as esotropia or exotropia (XT), whereas misalignment in the vertical axis is seen as hypertropia. But torsional misalignment is invisible to the clinician when the eyes are in primary position: Detection usually depends on observing the relatively skewed ocular deviations in various gaze directions, or on funduscopy by noting the incyclorotated or excyclorotated fundus appearance. Incyclotorsional misalignment is often attributed to SO OA, whereas excyclotorsion is often attributed to IO OA.

In human eyes, the actions of the extraocular muscles (EOMs) are not so cleanly separated along these axes. The horizontal recti are pure in their direction of action: Even in eccentric gaze, their muscle paths are constrained by the pulley system of the orbit. Because they originate on the nasally displaced orbital apex, the superior rectus muscle is responsible for modest intorsional effect, and the inferior rectus muscle for a modest extorsional effect. As a result, increased or decreased action of either

Fig. 11.8.1 A-pattern with superior oblique overaction (SO OA). (Courtesy L. R. Dagi, MD.)

**Fig. 11.8.2** V-pattern with inferior oblique overaction (IO OA) and superior oblique underaction (SO UA). (Courtesy L. R. Dagi, MD.)

**Fig. 11.8.3** Bilateral excyclotorsion. (Courtesy S. K. McClatchey, MD.)

vertical rectus muscle secondary to, for example, local toxicity from an anesthetic injection or inflammatory hypertrophy from thyroid eye disease can sometimes result in symptomatic torsional diplopia.<sup>2,3</sup>

The oblique muscles insert at an angle  $39^\circ$  from that required to be purely torsional, with the spread of SO insertion causing its effect to vary even more with ocular position. In addition, the passive action of orbital tissues and the elasticity of the EOMs have significant impact on the ocular position in eccentric gaze.

Each of the EOMs passes through a pulley of connective tissue that constrains its path, forming an effective point of origin for the action of the muscle as it inserts at the globe. These pulleys are connected in an array that encircles the globe. This array is actively shifted by the orbital layers of the EOMs and by smooth muscle. It has been demonstrated that rectus muscle transposition procedures have little impact on rectus muscle trajectory behind the globe because of the stabilizing effect of the pulley system. Thus, the very presence of this pulley system modulates the impact of transposition procedures and likely explains why such procedures leave the original function of the transposed muscle reasonably intact.<sup>4</sup>

In most patients, torsion is a key to understanding clinical observations.<sup>5,6</sup> However, pathology in any of these components, including neural control, muscles, soft tissues, and the pulley arrays, and, in some cases, even the bony orbital anatomy can produce strabismus, in particular, pattern strabismus and oblique overaction.<sup>7</sup> Recent work has identified neurally separate compartments of some of the extraocular muscles, which also may play a role in some cases.<sup>8</sup>

### Example: Child With Accommodative Esotropia Who Develops a V-Pattern

As an example of primary overaction of the inferior obliques, let us consider a common case of a 2-year-old child with hyperopia of  $+4.5$  D both eyes (OU) presenting with accommodative esotropia. Initial examination shows no oblique overaction, pattern strabismus, or fundus torsion, and wearing of glasses fully correct his deviation. The child is lost to follow-up, and over 2 years, he fails to wear the glasses. He presents again at age 4 years with now partially accommodative esotropia. When wearing glasses to correct his full cycloplegic refraction, his ET cc = 25 PD. He also has 3+ inferior oblique both eyes (IO OU), a moderate V-pattern, and approximately  $15^\circ$  of excyclotorsion in both eyes (Fig. 11.8.3). Because no apparent cause exists for IO OA, such as fourth cranial nerve palsy or craniosynostosis, it is diagnosed as primary IO OA. Surgery is performed: recess medial rectus (MR) 5.0 mm OU and recess IO 14 mm OU. At his 2-month postoperative examination, he is ortho in all positions of gaze, with no IO overaction, no V-pattern, and no torsion on fundus exam.

Why did this patient develop a V-pattern with apparent IO OA, and how did recession of IO correct both conditions?

### Summary of Upcoming Sections

Many causes occur for oblique overactions and pattern strabismus. In this chapter, we will show how ocular torsion and heterotopy of the pulley arrays

**Fig. 11.8.4** The top row displays fundus photographs of the direct view of anatomical (fundus) torsion progressing from no torsion to 4+ excyclotorsion. Below each photo the image is inverted to illustrate the view seen by the examiner with indirect ophthalmoscopy. (With permission from MacKinnon S, Rogers GF, Gregas M, Proctor MR, Mulliken JB, Dagi LR. Treatment of unilateral coronal synostosis by endoscopic strip craniectomy or fronto-orbital advancement: ophthalmologic findings J AAPOS 2009;13(2):155–60.)

are the keys to understanding many cases of oblique muscle dysfunctions and V- and A-pattern strabismus. We will discuss clinical observations, the place of torsion within the three axes of strabismus, how torsion of the rectus pathways results in pattern strabismus and the appearance of oblique overaction, how lack of fusion can lead to torsional strabismus in many, and other causes of oblique dysfunctions.

## CLINICAL OBSERVATIONS

### Epidemiology

In a study by Wilson and Parks,<sup>9</sup> IO OA was observed to develop in about 72% of patients with congenital esotropia, 34% of those with accommodative esotropia, and 32% of those with intermittent exotropia, who were followed up for longer than 5 years. The incidence of IO OA in patients with congenital esotropia was not related to age at strabismus onset, time from onset to surgery for the esotropia, age at first surgery, or decompensation of horizontal alignment; it was, however, related to the number of surgeries necessary to align the eyes horizontally. The mean age of onset or detection was 3.6 years with many demonstrating pattern deviation much before.

Eustis and Nussdorf<sup>10</sup> studied infants undergoing bilateral medial rectus muscle recession for esotropia and found that of the eyes with excyclotorsion observed at surgery, all demonstrated IO OA at follow-up. Of those with no torsion at the time of surgery, only nine of 21 demonstrated IO OA at follow-up.

Of children with SO OA, there is a higher rate of concurrent neurological disease, up to 40% in one series.<sup>11</sup>

### Age of Observation

Oblique overactions and A- and V-patterns rarely are observed clinically in very young infants with esotropia, perhaps because of their limited efforts. It is difficult to get an infant to follow an object into far side-gaze or to precisely measure alignment in chin-up or chin-down posture. Many patients either develop or are found to have these signs of torsional strabismus when they are 2–6 years of age.

### How to Observe or Measure Torsion

#### Directly With Fundoscopy or Photography

Clinical fundoscopy can be used to estimate the degree of fundus torsion, based on a 1– to 4+ scale,<sup>5</sup> a protractor,<sup>12</sup> or estimation of the angle, as is done for free-lens retinoscopy refractions. Torsion also can be documented by fundus photography in cooperative patients (Fig. 11.8.4) or at surgery.

### Correlation of the Appearance of Oblique Overaction, Pattern Strabismus, and Fundus Torsion

Clinically significant fundus torsion can vary from 10° to 20°. In general, 10° of bilateral fundus excyclotorsion corresponds to 2+ IO OU and a moderate V-pattern; 20° of excyclotorsion corresponds to 4+ IO OU and a large V-pattern. The same is true for incyclotorsion: 10° of bilateral fundus incyclotorsion corresponds to 2+ superior oblique both eyes (SO OU) and a moderate A-pattern; 20° of incyclotorsion corresponds to 4+ IO OU and a large A-pattern. With large angles of torsion, the eyes also appear to have underaction of the antagonist of the “overacting” oblique: thus a child with 20° of excyclotorsion may appear to have a 2– SO OU as well as 4+ IO. Of note, some children with craniosynostosis can have substantially larger torsion as a result of orbital torsion; the authors have seen up to 40° of excyclo-torsion in this setting.<sup>13</sup>

### Blind Spot Mapping

In eyes with ocular torsion, the relative position of the nerve and macula are rotated. Visual fields in such eyes show displacement of the blind spot, with the blind spot below the horizontal meridian in excyclo-torsion and above in incyclotorsion.<sup>6</sup>

### Location of Rectus Muscle Insertions at Surgery

An eye with significant excyclo-torsion maintains that torsion under anesthesia. Thus, a surgeon who makes an inferotemporal conjunctival incision will do so directly over the inferior border of the lateral rectus muscle insertion instead of over the sclera.

### Forced Ductions

Forced ductions at surgery of eyes with torsional strabismus can demonstrate limitations because of short oblique muscles.<sup>14</sup>

### Double Maddox Rod

An adult with acquired fourth cranial nerve palsy from injury to the trochlear nerve will show subjective excyclo-torsion on a Double Maddox rod (DMR) test. However, as shown by Guyton and von Noorden,<sup>15</sup> patients who develop torsion before age 6 years do not show this subjective finding. Analogous to anomalous retinal correspondence for horizontal strabismus, sensory adaptations occur in childhood torsional strabismus.

### Lancaster Red-Green Test

The Lancaster red-green test provides a clear plot of strabismus in these patients; in some, there is a clear torsional pattern.

**Fig. 11.8.5** Extorsion in both eyes (OU) resulting in V-pattern strabismus in attempted up- and downgaze. (Courtesy S. K. McClatchey, MD.)

### Magnetic Resonance Imaging of the Orbits

The fine detail of high-quality surface-coil magnetic resonance imaging (MRI) has been used to extensively document the muscle paths and connective tissue of the orbits. In some patients, such as those with craniosynostosis and pattern strabismus, the pulley array has been shown to be tortorted, incylo-tortorted for A-patterns and excylo-tortorted for V-patterns, or with certain pulleys displaced (heterotopy).<sup>16,17</sup> In other patients, especially those with high myopia, older adults, or those with connective tissue aging laxity, the pulley or muscle pathway pathology varies and is key to understand the resulting strabismus.

### Parks' Three-Step Test

The late Dr. Marshall Parks said that his three-step test was useful to identify the offending cyclovertical muscle only for an isolated cyclovertical paresis. In practice, this test works best with some patients who have an SO palsy, but when used in isolation, it sometimes does not help accurately diagnose even a palsied SO; other cyclovertical muscles are rarely paretic in isolation. There are many factors that confound the results of this test, such as skew deviation, pulley heterotopy, thyroid eye disease, and strabismus surgery; it can be frankly misleading.<sup>2,8</sup>

### Torsion Is Sufficient to Cause the Appearance of Oblique Dysfunction

#### A- and V-Patterns From Excyclotorsion of the Globe Absent Primary Oblique Dysfunction

As the vector forces of the vertical recti are tortorted along with globe and pulley torsion, excyclotorsion in upgaze results in simultaneous exodeviation and in downgaze results in esodeviation, producing a V-pattern (Fig. 11.8.5).

On right gaze in a patient with excyclotorsion OU, the left eye is adducted and elevated, and the right eye is abducted and depressed. However, this is elicited clinically by asking the patient to “follow” an object. Typically, a patient will fixate with the abducted eye, which can only be maintained if the patient also makes an effort to elevate that eye. This elevation affects both eyes, resulting in the right eye fixating on the object of regard, and the left eye appears to have an exaggerated elevation in adduction: this may be interpreted by the clinician as IO OA even if that is not the primary cause (Fig. 11.8.6).

If one eye sees poorly because of amblyopia or another cause, on abduction it will go up (in incyclotorsion) or down (in excyclotorsion) to allow the adducting eye to remain in the horizontal position.

The corresponding “underactions” on version testing are more difficult to observe but are nearly always present with large degrees of torsion. Typically, a patient with 20° of excyclotorsion will have the appearance of 4+ IO OU and 2– SO OU.

### The Observation of Normal Version Testing After Denervation and Extirpation (D&E) of the IOs

Thus, the appearance of oblique over- or underaction may not be completely dependent on the oblique muscles themselves. Sometimes, it is caused primarily by cyclorotation of the pulleys and associated rectus muscles. However, surgery on the oblique muscles, in many cases, can resolve the abnormal torsion of the globe and the A- or V-pattern. As an example, in some patients with extreme excyclotorsional strabismus (4+ IO, large V-pattern, 20° of excyclotorsion), some surgeons perform a denervation and extirpation (D&E) of the IOs.<sup>18</sup> Subsequent version testing shows no oblique dysfunction at all, either over or underaction. Because the IO has no active effect on the globe or on the pulley array after this surgery, the recti must themselves be responsible for producing the normal versions: the net effect of the D&E is to relieve the excyclotorsional effect of the shortened IOs.

## ETIOLOGY

### Sensory Torsion

#### Well-Known Examples of Sensory Esotropia or Sensory Exotropia

Children or adults who have poor vision in one eye often lose good binocularity and develop strabismus. For example, children with unilateral cataract in the Infantile Aphakia Treatment Study (IATS) had a 39% rate of strabismus surgery.<sup>19</sup> This is often called *sensory strabismus*. It is thought that the patient's underlying alignment tendency (bias) toward eso- or exodeviation results in gradually increasing esotropia or exotropia, respectively, through muscle length adaptation.<sup>20</sup>

### Muscle Length Adaptation

Muscles throughout the body continually remodel to conform to their average length, and the EOMs likewise lengthen and shorten in response to chronic ocular position.<sup>20</sup> This adaptation occurs by addition or subtraction of sarcomeres at the tendon–muscle connection.<sup>21</sup> In effect, a muscle that is chronically extended lengthens over time; muscles that are chronically

**Fig. 11.8.6** Extorsion in both eyes (OU) results in “left inferior oblique overaction” in attempted right gaze. (Courtesy S. K. McClatchey, MD.)

**Fig. 11.8.7** Muscle length adaptation results in the length of the inferior oblique being shorter when the eye is chronically extorted; the antagonist superior oblique is likewise lengthened. (Courtesy S. K. McClatchey, MD.)

in a shortened state shorten over time. Muscle length adaptation allows the muscles to grow as the body grows in childhood and has a large role in many pathological states, such as muscle contractures in cerebral palsy.

Thus, there is some sense to the admonition, “Don’t cross your eyes like that, or they’ll get stuck!” Because of muscle length adaptation, the extraocular muscles of eyes that are chronically misaligned lengthen or shorten to match their chronic position; this explains the development of nonaccommodative esotropia over time in a patient with uncorrected accommodative esotropia. Some other examples of this include normal development (the muscles lengthen to match the growing orbit), the lengthening of a recovered muscle 3 months after Botox injection, and spread of comitance over time in chronic fourth cranial nerve or sixth cranial nerve palsies.

### Bias

People with binocular fusion maintain alignment through a feedback process. Any misalignment of the eyes whether horizontal, vertical, or torsional is detected by the brain and corrected through a vergence reflex; in turn, the EOMs adapt to this normal alignment through muscle length adaptation. However, loss of fusion often allows any underlying bias to result in a freewheeling progressive misalignment in any of the three axes of strabismus, again reinforced through muscle length adaptation.

### Sensory Deprivation or the Lack of Fusion Leads to Tropia

If a patient has a bilateral horizontal outward bias, loss of fusion will result in exotropia over time, and inward bias results in esotropia. Vertical bias

tends not to cause tropia because the yoke vertical recti tend to be biased equally. Oblique bias, in turn, causes intorsion or extorsion through the same mechanism (Fig. 11.8.7). This oblique bias becomes manifest whenever fusion is lost because of any cause; most commonly, this occurs in horizontal strabismus and is called *primary oblique overaction* but is better termed *sensory torsion* in analogy to *sensory esotropia*.<sup>5</sup> Although these biases can be in any direction, in children, notably, sensory esotropia and sensory excyclotorsion tend to develop more frequently compared with exotropia and incyclotorsion.

Therefore, in patients who develop constant strabismus, such as congenital esotropia or partially accommodative esotropia, the lack of fusion allows the freewheeling obliques to steadily shorten or lengthen, depending on their inherent oblique bias, resulting in torsional strabismus.

### Pulley Arrays

Pioneering computer modeling by Joel Miller<sup>22</sup> demonstrated that muscle paths must be constrained by a pulley system, which has been identified by histological studies, high-resolution MRI, and studies in animals. The constraints of pathologically torted pulley arrays result in pattern strabismus in certain patients, such as those with craniosynostosis.

Each of the six extraocular muscles passes through a pulley before inserting on the globe. The trochlea of SO is fixed to the orbit, but the other pulleys consist of soft tissue condensations with a connecting ring of collagen and smooth muscle that serve as an array to constrain the path of

the muscles as they approach the globe. These pulleys are located behind the equator of the eye and are located close to where the muscle penetrates Tenon's capsule; it is coupled to the orbit by connective tissue. Each of the recti and oblique muscles have an active orbital layer that inserts on the pulley array so that on muscle contraction the array is shifted by the recti or torted by the obliques along with ocular motion, although less so than the globe itself.<sup>8</sup> This active pulley array enforces Listing's law and greatly simplifies the effect of neural input to the EOMs in various gaze positions. The pulley array also can be adversely affected by aging, high myopia, and other pathology; the discussion of these conditions is beyond the scope of this chapter.

The whole array can be excyclotorted in patients with craniosynostosis, resulting in large V-patterns, the appearance of large IO or SO overactions, and a tilt of the palpebral fissure matching the torsion. In V-patterns, the palpebral fissures are temporally down-slanted; those who present with the less common A-patterns may demonstrate upward slanting of the fissures.

Although the cyclovertical muscles may have oblique pathways in the primary or off-axis position, the pulleys constrain their actions in all gaze directions. In secondary or tertiary gaze, these pulleys are the inflection points of the muscle paths. To a great degree, the superior and inferior recti act vertically, and the primary action of the SO and IO is torsional. These constraints greatly simplify the brain's task in maintaining fusion as the eyes move together.

## Other Causes of Oblique Dysfunctions and Pattern Strabismus

Often these are called *secondary oblique overactions*.

### Superior Oblique Muscle Palsy

Congenital SO "palsy" can either be from a true SO underdevelopment, as seen on orbital MRI, or from a laxity of the tendon found by forced ductions or direct observation at surgery. Fourth cranial nerve palsies may also be acquired, from trauma, tumor, or myasthenia gravis. DMR testing in acquired cases shows subjective torsion. The antagonist muscle (the IO) shortens over time, and the excyclotorsion from both causes appears as IO overaction and SO underaction.

### Brown's Syndrome

Patients with Brown's syndrome have an outward deviation of the Brown eye in far upgaze, simulating a V-pattern. There is, however, no predictable pattern of torsion for either eye in primary position.

### Duane's Syndrome

Eyes with Duane's syndrome can simulate IO or SO overaction because of a tight lateral rectus muscle or because of abnormal neural stimulation of the vertical recti—again, as such, small amounts of fundus torsion may be noted on examination.

### Dissociated Vertical Deviation

Dissociated vertical deviation (DVD) can appear similar to IO OA on version testing and often appears in the same patient population, but several distinguishing features occur. As opposed to excyclotorsion, DVD is apparent in the primary position and is usually accompanied by latent nystagmus. No true hypertropia of the adducting eye exists in side-gaze, although often DVD will appear when the visual axis of the adducting eye is blocked by the nose. Unless there is a coexisting torsional strabismus, no V-pattern or fundus torsion occurs.

### Craniosynostosis

Many patients with craniosynostosis, such as those with Crouzon's or Apert's syndrome, have congenitally excyclorotated orbits, resulting in large V-patterns and corresponding oblique overactions. A-patterns are less commonly seen. Most commonly the pulley array is excyclotorted,<sup>23</sup> and the appearance of seeming IO OA and superior oblique underaction (SOUA) is seen. It is, however, important to note that the exaggerated V-patterns seen in some forms of craniosynostosis also may be the result of seemingly absent,<sup>24</sup> but most likely underdeveloped extraocular muscles, and iatrogenic disinsertion of the SO at the trochlea during primary craniofacial repair (fronto-orbital advancement).<sup>25</sup> Particularly exaggerated V-patterns associated with exceptional amounts of fundus torsion and, in some cases, inability to elevate the abducted eye above midline (the "see-saw" V-pattern), may be secondary to alteration in the bony anatomy of the orbital apex.<sup>13</sup> This causes primary excyclotorsion of the rectus muscles initiating at the very origins of the rectus muscles near

the orbital apex, and likely reinforced by secondary pulley heterotopy.<sup>13</sup> Of note, oblique muscle surgery by itself often has only modest effect in such patients because of the multifactorial origin of the V-pattern.<sup>26</sup>

## Pseudo-Oblique Overaction Occurs in Patients With a Large Quantity of Exotropia

As shown by Capo et al.,<sup>27</sup> patients with large-angle exotropia can appear to have simultaneous SO OA and IO OA on both sides. No torsion exists in such patients, and the oblique overactions normalize with horizontal rectus surgery for the exotropia alone. This occurs as a result of the mechanics of the soft tissues in the orbit, which limit rotation of the globe.

## MANAGEMENT

### Observation

Small or moderate torsional strabismus may have little effect on the patient's function or appearance. Patients with a moderate V-pattern but otherwise straight eyes will have esotropia on downgaze, but most patients are fixating at near when looking down, so this can be a physiological alignment.

Some patients adopt a head posture to maintain binocularity; this posture usually indicates a need for surgical treatment. For example, a child with good binocularity and a V-pattern esotropia might develop a chin-down posture to maintain fusion.

### Oblique Muscle Surgery

Surgical management of torsional strabismus often is undertaken simultaneously with surgery for horizontal misalignment. Correction generally involves moving the insertion of the IO for excyclotorsion, or operating on the SO tendon to increase or diminish incyclotorsion. In surgery for horizontal strabismus, the recti are neither strengthened nor weakened. To a good approximation, the muscles are cut off, the globe is repositioned, and the muscle insertions are replaced in the new position.<sup>28</sup> In the same way, one common treatment for extorsion consists of cutting the IO, returning the globe to its normal position, and replacing the oblique insertion passively (myectomy) or actively (via recession). The SO with its broad insertion has a more complex mechanical effect than the IO, varying more with globe position. Although an SO recession can be performed,<sup>29,30</sup> intorsion is sometimes treated with SO tendon lengthening via a graded expander.<sup>31,32</sup> Likewise, extorsion or insufficient intorsion can be treated with an SO tuck (e.g., in congenital "SO palsy" caused by a lax tendon) or a Harada-Ito procedure.

Bilateral symmetrical SO or IO surgery typically has no effect on the horizontal alignment.<sup>11,33</sup>

Any surgery that affects ocular torsion in a patient with stereopsis will cause a postoperative sensation of everything appearing to be tilted toward or away from the patient. This occurs because the change in torsion results in a relative horizontal displacement between the two eyes, of objects above or below the object of regard—the same phenomenon used by the stereopsis system to judge distance. The same phenomenon occurs when a patient is given spectacles that correct oblique astigmatism with opposing directions in the right and left eyes. In these cases, it is useful to provide a warning to the patients that they will experience such symptoms for about 2 weeks after surgery.

### Surgical Variations

IO surgery has several variations. The IO can be recessed along its path: 10 mm for 2+ IO OA and 14 mm for 3+ IO OA. A myectomy of the IO allows the globe to untort and has proven suitable for a remarkably wide range of IO OA in a self-correcting manner. In large V-patterns and 4+ IO OA, a D&E eliminates the active effect of the muscle. In patients with combined DVD and moderate V-pattern or 2+ IO OA, anterior transposition of the insertion to a station just temporal to the lateral border of the inferior rectus muscle can both correct the torsion and reduce the DVD.

Surgery on the SO is more complex but also has several variations. For large A-patterns in nonbinocular patients, tenotomy or tenectomy will collapse the pattern; this must be avoided in patients with binocularity because it may produce intractable diplopia. Other variants to treat incyclotorsion that permit a more controlled "weakening" of SO tone and incyclotorsion include Z-split lengthening of the tendon, graded recession of the SO,<sup>29,30</sup> silicone tendon expander,<sup>31</sup> and intraoperative adjustable suture expander,<sup>32</sup> among others. A tuck of the SO works well to correct

congenital SO palsy, where forced ductions reveal a laxity of the tendon. Harada–Ito advances or tucks the anterior fibers of the SO tendon and can successfully increase incyclotorsion or reduce excyclotorsion in a measured or adjustable manner.

## Rectus Transpositions

Rectus muscle transposition may be used to resolve A- or V-patterns. For example, for a V-pattern, the medial recti would be transposed inferiorly or the lateral recti transposed superiorly. In the absence of primary oblique dysfunction, vertical transposition can be effective; such transposition may, however, worsen torsion and, in that regard, is less suitable for the patient with good stereopsis.<sup>34</sup>

## SUMMARY

The young boy, in our example, with partially accommodative exotropia, IO OA, V-pattern, and excyclotorsion can best be understood as having strabismus in two axes, horizontal and torsional. Accommodation to see through uncorrected hyperopia forced his eyes inward via the near triad reflex. The excyclotorsion developed when his eyes crossed and lost fusion as a result of this accommodative esotropia. The loss of fusion allowed his underlying excyclotorsional bias to drive a progressive shortening of his IOs and lengthening of his SOs through muscle length adaptation, just as his medial recti shortened through muscle length adaptation to their chronically shortened position. Thus, this strabismus caused by loss of fusion that allows the freewheeling torsional bias to gradually induce bilateral ocular torsion through muscle length adaptation is best termed *sensory torsion*. The main surgical effect of bilateral recession of the medial recti and bilateral recession of the IOs is, thus, to address each of these component axes separately.

The clinician must keep in mind that there are many causes of ocular torsion, pattern strabismus, and the appearance of oblique dysfunction. Careful measurements in the three axes of strabismus and a search for all potential causes can yield a better understanding of the nature of the strabismus and guide surgical treatment.

# Paralytic Strabismus

Hilda Capó, Steven E. Rubin

# 11.9

**Definition:** Strabismus resulting from partial or complete paralysis of the third, fourth, or sixth cranial nerve.

## Key Features

- Incomitance—magnitude of deviation is gaze dependent.
- Secondary deviation—magnitude of deviation increases when paretic or restricted eye is fixating on a target.

## Associated Features

- Third nerve palsy—ipsilateral exotropia, hypotropia, ptosis, and pupillary findings.
- Fourth nerve palsy—ipsilateral hypertropia with head tilt to the opposite side.
- Sixth nerve palsy—ipsilateral esotropia with head turn to the affected side.

## INTRODUCTION

The most common type of strabismus is the comitant variety—in which the angle of deviation does not vary with direction of gaze. Less commonly, oblique muscle dysfunction causes an alphabet-pattern strabismus, as discussed in Chapter 11.8. Least common are the disorders that result from paresis or restriction of the extraocular muscles. This chapter discusses only paralytic strabismus.

In contrast to the straightforward evaluation of comitant strabismus, an expanded array of diagnostic techniques must be employed in patients with paralytic strabismus. Accurate classification of strabismus requires measurements in the cardinal positions of gaze (as discussed in Chapter 11.3) to detect the characteristic incomitance of paretic or restrictive disorders. In general, the measured deviation is greatest in the field of action of the paretic muscle(s).

With comitant strabismus, prism measurements are independent of the fixating eye, even in patients with a fixation preference for one eye. If the measurements change when the fellow eye takes up fixation, a paretic or restrictive etiology is usually the cause. The deviation is larger when the affected eye is used for fixation and is termed *secondary deviation*.

Restriction can be confirmed by forced duction testing, whereby the anesthetized perilimbal conjunctiva of the affected eye of a cooperative patient is grasped with forceps and the eye moved into the affected field; resistance indicates mechanical restriction (pointing to contracture of the antagonist muscle) rather than, or in addition to, muscle weakness as the cause of the strabismus. To confirm a paretic process, force generation testing to assess the relative strength of a muscle is useful. The anesthetized perilimbal conjunctiva is grasped with forceps and the patient instructed to look in the affected field<sup>1</sup> as the examiner feels the pull of the affected muscle. Similar information can be gained from careful observation of saccades into the limited field. A steady but slow movement into the gaze direction in question suggests a paretic cause, in contrast to an initially rapid and abruptly ending movement (like a dog running to the end of its leash), which suggests a restrictive cause. A Tensilon test also should be considered, as myasthenia gravis can mimic any isolated or combined extraocular muscle palsy.

Diplopia in adults and cooperative children can be assessed with binocular visual fields. This technique utilizes a standard Goldmann perimeter

or tangent screen to identify and quantify the extent of the diplopic areas of gaze.<sup>2</sup>

Patients with extraocular muscle palsies require consideration for more extensive evaluation. Comitant strabismus is rarely secondary to a neurological or systemic disease, whereas paralytic strabismus can result from other disorders. Congenital palsies are the main cause in children and can be the cause of fourth nerve palsies in adults, who may maintain their deviation latent for many years.

Management of paralytic strabismus follows the same general guidelines as for many difficult conditions—less invasive and less risky remedies are tried first. Hence, patients with a mild or slowly improving paresis can be offered occlusion or prism therapy before surgery is considered. Surgical treatment should be deferred until more than 6 months have passed after onset and serial examinations yield stable results. Before proceeding with surgery, the precise goals of treatment must be made exceedingly clear to the patient. The primary goals are to attain good ocular alignment in the primary position and downgaze, improve the incomitance, expand the field of single binocular vision, and improve compensatory head postures. Achieving good alignment in all fields frequently is unfeasible. When surgery is planned, the muscle(s) at work in the field(s) of greatest deviation must be targeted. Although advocated by some for routine use in all cooperative patients undergoing strabismus surgery, adjustable sutures have an even greater potential role in surgery for paralytic strabismus. The great variability in the degree of weakness of affected muscles makes published tables of graded recessions and resections somewhat less reliable in nerve palsies. Appropriate informed consent for surgery requires a discussion about alternative treatments, including the option of no treatment. Details of surgical strategies are discussed with the individual nerve palsies.

## THIRD NERVE PALSY (OCULOMOTOR)

### Introduction

Because the third cranial nerve innervates the inferior oblique, inferior rectus, and medial rectus muscles (by its inferior division) and the superior rectus and levator muscles (by its superior division), palsy of this nerve can affect ocular motility in all three planes (horizontal, vertical, and torsional).

### Ocular Manifestations

Third nerve palsies typically manifest ipsilateral exotropia and hypotropia with ptosis and pupillary findings. They can be congenital or acquired and can be partial, affecting one or more muscles (Fig. 11.9.1) or complete (Fig. 11.9.2). Cyclic palsies also have been reported.<sup>3</sup>

Aberrant regeneration is a phenomenon peculiar to third nerve palsies, hence the alternative term *oculomotor synkinesis*. After a paretic event, the extramedullary axons can heal and regenerate, but not necessarily to their original locations.<sup>4</sup> Therefore, action potentials that previously resulted only in adduction may now produce depression, retraction (from simultaneous vertical rectus muscle contraction), globe elevation, lid elevation, or pupillary constriction. The two most common manifestations are lid elevation (pseudo-Graefe sign) and pupillary constriction, each of which occurs on adduction, downgaze, or both.

### Congenital Third Nerve Palsies

Congenital third nerve palsies (generally idiopathic) are rare. Affected children most often have unilateral involvement and no other neurological abnormalities.<sup>4</sup> Some of the latter have been reported<sup>5</sup> but are thought to represent concurrent injury rather than a cause of the palsy. These cases

**Fig. 11.9.1 Adult With a Partial Left Third Nerve Palsy.** (A) Primary gaze showing slightly larger pupil, mild ptosis, left exotropia, and left hypotropia. (B) Normal left gaze. (C) No adduction of the left eye on right gaze. (D) Poor elevation. (E) Poor depression.

are not considered traumatic in origin as excessive birth trauma is not consistently found.

Most often, in congenital palsies all the extraocular muscles innervated by the third cranial nerve are affected, resulting in exotropia, hypotropia, and ptosis of varying amounts. Pupillary involvement can result from either a primary manifestation of the palsy (a larger pupil from deficient sphincter innervation) or aberrant regeneration (pupillary constriction

**Fig. 11.9.2 Older Woman With Complete Left Third Nerve Palsy.** (A) Complete ptosis, left eye. (B) Left exotropia and (small) left hypotropia.

**TABLE 11.9.1 Causes of Acquired Third Nerve Palsy by Age Group**

Cause	Children (%)	Adults (%)
Trauma	40	14
Neoplasm	14	11
Aneurysm	0	12
Vascular/diabetic	0	23
Other	29	16
Undetermined	17	24

with adduction or downgaze). Pupillary sparing is not a reliable indicator of congenital origin as its presence in congenital cases is inconsistent.<sup>4,6,7</sup> Most children suffer loss of binocular function and amblyopia from ptosis or constant exotropia. When ptosis is either absent or incomplete, to optimize their binocularity, affected children may develop an abnormal head posture (torticollis) consisting of chin elevation or a contralateral face turn to neutralize the hypotropia, ptosis, or exotropia.

### Acquired Third Cranial Nerve Palsies

Acquired third nerve palsies, although more common than their congenital counterpart, are still unusual. They are rarely bilateral. Possible causes are age dependent (Table 11.9.1). The incidence is low among children and young adults, in whom trauma is the most common cause, but increases in middle-aged adults (1.7 per 100,000).<sup>8</sup> Patients older than 60 years have the highest incidence (12.5 per 100,000), predominantly because of a large increase in microvascular third nerve palsies.<sup>8</sup> Acquired palsies of the oculomotor nerve produce an incomitant exotropia and/or hypotropia and/or ptosis. In addition, visually mature adults report diplopia and visual confusion unless they also have significant ptosis. Torticollis (contralateral face turn and/or chin-up posture) develops if the posture neutralizes the diplopia.

Patients with an acquired third nerve palsy require further neurological evaluation as the palsy may be an ominous sign, especially in younger patients,<sup>9,10</sup> although exceptions occur.<sup>11</sup> Once thought indicative of benign and non-life-threatening microvascular disease, pupillary sparing can occur even in cases caused by intracranial aneurysms.<sup>12–14</sup> Pain and pupil involvement are unreliable in differentiating a microvascular from aneurysmal compression (see Chapter 9.16, for specific details and recommendations for evaluating these patients). Isolated pareses of individual muscles innervated by either branch of the third cranial nerve have been described<sup>15</sup> and generally defy neuroanatomic localization. They are almost never indicative of serious pathology elsewhere, and manifestations depend on the affected muscle. Brown's syndrome must be considered

in a patient with an apparent isolated inferior oblique muscle palsy; the three-step test (discussed later) and forced duction testing usually can distinguish between these two conditions. In patients who have craniofacial disease, isolated pareses may be caused by congenital absence of a rectus or oblique muscle.<sup>16</sup> Abnormal horizontal insertions also have been reported.<sup>17</sup>

## Nonsurgical Treatment

Third nerve palsy is the most challenging of the paralytic strabismus syndromes because of the number of muscles and different motility planes involved. Definitive treatment is almost never immediately required because many cases exhibit some degree of improvement, either spontaneously or when the underlying cause is managed.

In visually immature children, careful attention must be paid to both monocular and binocular visual development during this period because amblyopia can develop rapidly and require aggressive patching. In visually mature individuals without complete ptosis, diplopia may be alleviated with occlusion during the period of expectant observation. Even incomplete occlusion, accomplished by applying translucent tape to a spectacle lens, may be sufficient. When the horizontal or vertical deviation is small, prisms may be beneficial to keep binocular development on track in children and alleviate diplopia in adults. Prisms may be a permanent solution when the residual deviation is small. Although prisms work best in small comitant deviations, success in incomitant strabismus is possible if the magnitude of the prism is chosen to match the functionally important primary and downgaze positions.

Botulinum toxin therapy can be a useful adjunct treatment in the acute phase. Injecting the antagonist muscle(s), either by direct surgical visualization or transconjunctivally under audible electromyographic control, can prevent permanent contracture, which would otherwise interfere with recovery or complicate subsequent surgical treatment, or both.<sup>18–20</sup>

## Surgical Treatment

Restoration of normal motility generally is not attainable except in the mildest cases, so realistic surgical goals should be made clear to the patient in the early stages of treatment. Surgical treatment should be undertaken when little if any expectation of additional recovery exists, usually at least 6–12 months after onset. When some medial rectus muscle function is present, a large recess–resect procedure may produce acceptable results for the horizontal deviation<sup>21,22</sup>; this has been advocated in some patients with complete paralysis if combined with a traction suture.<sup>23,24</sup> The resected medial rectus can be supra-placed or infra-placed to improve an associated vertical deviation.

Resections of completely nonfunctional muscles have limited long-term effect as the nonfunctioning muscle stretches with time. Therefore, when no demonstrable medial rectus function exists, some other method to generate passive adducting force is necessary in addition to functional inactivation of the lateral rectus muscle. The latter requires supra-maximal recession of the lateral rectus muscle to at least 16 mm from the original insertion,<sup>25</sup> fixation of the lateral rectus muscle to the periosteum of the lateral orbital wall,<sup>26</sup> or extirpation or large myectomy of the lateral rectus muscle. Passive adducting force can be accomplished by transposition of the superior oblique tendon<sup>27</sup> insertion to a position adjacent to the medial rectus insertion, either with<sup>28</sup> or without<sup>29</sup> its removal from the trochlea. Additional alternatives include nasal orbital fixation and nasal transposition of the lateral rectus muscle. Nasal orbital fixation of the eye globe may be accomplished utilizing various materials, including an orbital bone periosteal flap,<sup>30,31</sup> a nonabsorbable suture anchored to the medial orbital wall periosteum,<sup>32–34</sup> or a T-plate titanium anchoring system fixated to the medial orbital wall.<sup>35</sup> Transposition of the lateral rectus muscle to the superior and inferior borders of the medial rectus muscle,<sup>36</sup> in combination with adjustable sutures<sup>37</sup> or augmented fixation sutures,<sup>38</sup> may generate adducting force and eliminate the opposing force of the lateral rectus muscle. Adequate splitting of the lateral rectus muscle is critical when performing nasal transposition to avoid compromising the optic nerve.

An accompanying ptosis generally is addressed after ocular alignment has been optimized. If done in reverse order, raising the lid of a hypotropic eye unable to utilize Bell's phenomenon to protect the cornea may produce exposure keratitis and worsen diplopia. This strategy may, however, have to be followed in visually immature children to prevent the development or worsening of amblyopia.

With isolated muscle palsies, the prognosis for an acceptable outcome is greater because only one muscle is affected. Such pareses are generally

treated by weakening the antagonist muscle along with strengthening (resection) of the affected muscle, provided some of its function remains. In the case of isolated inferior oblique muscle paresis, antagonist weakening (of the superior oblique muscle) must be done with caution because of the resulting effects on ocular torsion. In such cases, vertical rectus muscle weakening also can be effective.<sup>39</sup>

Whenever performing surgery on multiple rectus muscles on the same eye, anterior segment ischemia (ASI) is a possible complication. This condition may result when perfusion of the anterior segment is abruptly compromised by sudden loss of the contribution made from the anterior ciliary arteries that normally accompany the rectus muscles and penetrate the sclera at the muscle insertions. The vertical rectus muscles generally contribute more than the horizontal rectus muscles do. With time, perfusion to the anterior segment is restored by augmented circulation from the posterior ciliary circulation. This lends support to the strategy of staging surgery and waiting several months to operate on additional muscles on the same eye. ASI can occur years after the initial extraocular surgery<sup>40</sup> or even after surgery on only two muscles.<sup>41</sup> Acute manifestations of ASI include pain, corneal edema, Descemet's membrane folds, and anterior chamber inflammation. Late effects include iris atrophy, an eccentric pupil, and sometimes visual loss.<sup>42</sup> Although ASI usually arises only with surgery on three or four rectus muscles, circumstances such as circulatory disorders or advanced age can increase the risk with surgery on fewer muscles. Preservation of the anterior ciliary circulation during rectus muscle surgery, either with<sup>43</sup> or without<sup>44</sup> the use of the operating microscope, has been proposed to reduce if not eliminate the risk of this complication (discussed in Chapter 11.13).

## FOURTH NERVE PALSY (TROCHLEAR)

### Introduction

Palsies of the fourth (and sixth) cranial nerves generally are less complex clinical pictures because these two cranial nerves each innervate only one extraocular muscle. The fourth cranial (trochlear) nerve controls the superior oblique muscle, which acts as a depressor and is the major intorter of the eye.

### Epidemiology and Pathogenesis

Although incidence data are age dependent, large series generally indicate that palsies of the fourth cranial nerve occur less often than those of the third cranial nerve<sup>21,45–47</sup>; pediatric studies show that order reversed.<sup>48</sup> Data from a practice based on strabismus surgery, however, might indicate that fourth nerve palsies are the most common.<sup>15</sup> The ability of patients to maintain latency of fourth nerve palsy (as a result of development of large vertical fusional amplitudes) probably influences the reported statistics.

Fourth nerve palsies rarely have a neurological etiology. Most cases are congenital (idiopathic) or posttraumatic in origin.<sup>4,49</sup> The fourth cranial nerve is uniquely susceptible to trauma<sup>50</sup> because it is the only cranial nerve with a dorsal exit from the brainstem, which results in the longest intracranial course of any cranial nerve. A patient who has a “unilateral” palsy, especially in traumatic cases, should be meticulously examined for evidence of bilateral involvement, which may not become evident until after surgery.<sup>15</sup> When a history of recent major trauma is lacking, a neurological workup may be considered but is usually unproductive.

Congenital fourth nerve palsy is almost always sporadic; only rare reports of familial occurrence exist.<sup>51,52</sup> Although the diagnosis in many patients is not made in childhood or youth, inspection of old photographs often reveals a consistent characteristic head tilt. Patients also commonly exhibit facial asymmetry, as discussed below. Amblyopia almost never is a complication in congenital or early acquired cases.<sup>53</sup> In rare cases, fourth nerve “palsy” results from congenital absence of the superior oblique tendon or muscle,<sup>54</sup> especially in patients who have craniofacial disorders.<sup>16</sup> This can be suspected preoperatively on finding an associated horizontal deviation, amblyopia, a large primary-position hypertropia, spread of comitance, and/or pseudo-overaction of the contralateral superior oblique muscle.<sup>55</sup>

### Ocular Manifestations

Weakness of the superior oblique muscle allows unopposed action of its direct antagonist, the inferior oblique muscle, which results in an ipsilateral hypertropia and excyclotorsion. Vertical diplopia and difficulty reading in downgaze are the most common complaints vocalized in fourth nerve

**Fig. 11.9.3** Young woman with idiopathic (presumed congenital) left fourth nerve palsy. (A) Primary position left hypertropia from loss of the depressor effect of the paretic left superior oblique muscle. (B) Normal motility in left gaze, away from the fields of action of the paretic left superior oblique muscle. (C) Compensatory overaction of the antagonist left inferior oblique muscle in its field of action in right gaze. (D) No vertical deviation on contralateral head tilt, when reflex excyclotorsion of the affected left eye is accomplished by the unaffected inferior rectus and inferior oblique muscles. (E) Large left hypertropia on ipsilateral head tilt, when reflex incyclotorsion recruits the superior rectus muscle and the paretic superior oblique muscle, and the vertical effect of the unaffected superior rectus muscle cannot be neutralized by the paretic superior oblique muscle.

palsy. Some observant patients also report excyclotorsion; affected engineers even draw the equivalent of Lancaster screen findings, including the effect on torsion.

The classic sign of unilateral fourth nerve palsy is a contralateral head tilt (an ocular torticollis). It is exhibited by most patients and is usually the presenting sign in children, although nonophthalmological causes also must be considered.<sup>56</sup> With a contralateral head tilt, reflex compensatory ocular countertorsion of the affected eye recruits the inferior oblique and inferior rectus muscles to produce excyclotorsion and avoids stimulation of the paretic superior oblique. When the inferior oblique and inferior rectus muscles produce this reflex countertorsion, their opposite vertical effects are mutually neutralized and no vertical deviation results, allowing the patient to maintain fusion. However, with an ipsilateral tilt (to the side of the paretic eye), the countertorsion of the affected eye recruits the incyclotorters, the superior rectus and paretic superior oblique muscles. The vertical effect of the normal superior rectus muscle, which produces elevation, is insufficiently neutralized by the weakened superior oblique muscle, resulting in an ipsilateral hypertropia<sup>57</sup> (Fig. 11.9.3). Paradoxically, some patients maintain a head tilt to the ipsilateral side, presumably to increase the vertical separation between the images and make it easier simply to ignore one of them.<sup>58</sup>

The Bielschowsky three-step head-tilt test<sup>59</sup> can be used to confirm the presence of an isolated cyclovertical muscle palsy if vision in each eye is adequate for fixation and no restrictions on either globe exist. It must be performed with the patient erect, otherwise the vestibular input, which this test is heavily dependent on, will be eliminated. The test was modified by Parks<sup>60</sup> and is now termed the *three-step test* (summarized in Table 11.9.2). Each of the three steps consists of an alternate cover test measurement of the deviation in the indicated gaze position(s): primary position for step 1, right and left gaze for step 2, and 45° head tilt to each side for step 3. Table 11.9.3 summarizes the eight possible outcomes of the three-step test as well as which of the eight cyclovertical muscles is the culprit. It is important to remember that a positive result of the three-step test does not prove the existence of an isolated muscle paresis<sup>61</sup>—it may be positive because of other causes, such as Brown’s syndrome. Torsion can be noted subjectively

**TABLE 11.9.2** The Three-Step Test for Diagnosis of an Isolated Single Cyclovertical Muscle Palsy

Step	Determine Whether:
1	There is a right or left hypertropia in primary gaze
2	The hypertropia worsens with right or left gaze
3	The hypertropia increases with right or left head tilt

**TABLE 11.9.3** Characteristic Three-Step Test Patterns and Their Interpretation

Test Outcome (Step 1–Step 2–Step 3)	Affected Cyclovertical Muscle
R–L–R	Right superior oblique muscle
L–R–L	Left superior oblique muscle
L–L–L	Right inferior oblique muscle
R–R–R	Left inferior oblique muscle
L–L–R	Left inferior rectus muscle
R–R–L	Right inferior rectus muscle
L–R–R	Right superior rectus muscle
R–L–L	Left superior rectus muscle

This test requires each eye to have vision sufficient for fixation and no restrictions. The test is not helpful in patients who have more than one weak cyclovertical muscle in each eye and may be positive in patients with Brown’s syndrome, muscle entrapment, or other causes of restricted eye movement.

through Maddox rod testing or objectively by comparing the spatial relationship of the fovea to the optic nerve on retinal examination.

Patients with bilateral palsy often have “reversing” hypertropias (e.g., a right hypertropia on left gaze and a left hypertropia on right gaze) and a bilaterally positive third step of the three-step test (right hypertropia on right head tilt and left hypertropia on left head tilt). A bilateral palsy often causes a chin-down head position in response to a V-pattern esotropia,

resulting from the loss of the superior oblique muscle's tertiary abducting action in downgaze and large degrees of excyclotorsion in downgaze.

Although symptoms of cyclotropia should be evident in any acquired fourth nerve palsy, it is often not a significant problem except in acquired bilateral cases, which typically result from closed head trauma. In congenital or early acquired cases, sensory reorientation of the retinal meridians develops to eliminate subjective cyclotropia.<sup>62,63</sup> When both superior oblique muscles are weak or completely paralyzed, their opposing hypertropias can neutralize each other, but their excyclodeviations are additive. This effect is maximized in downgaze, the field of greatest action of both superior oblique muscles. When the excyclotorsion (as measured by double Maddox rod [DMR]) exceeds 10°<sup>64</sup> or 15°, <sup>65,66</sup> a bilateral fourth nerve palsy is strongly suggested, although smaller amounts of torsion do not rule out a bilateral palsy.<sup>49</sup> Such affected patients, having no hypertropia to cause them to develop a compensatory head tilt, may adopt a chin-down head position to keep their eyes in the upgaze position where the paretic superior oblique muscles contribute least to ocular alignment, minimizing the excyclotropia and V-pattern esotropia. Observation of the relative positions of the disc and fovea with indirect ophthalmoscopy can be used to objectively assess torsion.<sup>67,68</sup>

Congenital or long-standing fourth nerve paresis can cause physiological and anatomical changes that help determine the time of onset. These patients are constantly challenged to maintain fusion despite a slowly increasing vertical deviation, allowing very large vertical vergence amplitudes to develop; 15–20 prism diopters (PD) are not unusual in these patients, a normal value being 3 to 4 PD.<sup>69</sup> In addition, the constant head tilt is strongly associated with facial asymmetry; the ipsilateral side is vertically shortened and hypoplastic. In such patients, a line drawn through both pupils and another line drawn through the corners of the mouth intersect near the face on the side of the tilt instead of running parallel as in patients with symmetrical facies. The asymmetry was once thought to result from ipsilateral carotid artery compression, but more recent work suggests that it is caused by deformational molding from monotonous ipsilateral positioning during sleep.<sup>70</sup> Early surgery in congenital cases is thought to prevent this asymmetry.<sup>70,71</sup>

## Nonsurgical Treatment

General principles of treatment apply in fourth nerve palsies—small, asymptomatic deviations usually can be observed until they produce a bothersome head tilt or other discomfort. In children, a persistent head tilt can even induce scoliosis.<sup>72</sup>

Small, symptomatic deviations, in some cases, may be successfully treated with the use of prisms. Even though incomitant deviations are not ideal indications for prism treatment, some palsies exhibit spread of comitance that makes them amenable to prism therapy. In cases without spread of comitance, prisms still may be successfully used by addressing the primary position and downgaze deviations and by taking advantage of the patient's large vertical fusional amplitudes.

As with other nerve palsies, acquired fourth nerve palsies, usually traumatic, should initially be nonsurgically treated during a period of observation lasting at least 6 months; improvement or even complete resolution frequently occurs. However, unlike their third nerve counterparts, congenital fourth nerve palsies almost always progress to the point where surgery becomes necessary.

## Surgical Treatment

Surgical treatment of fourth nerve palsies follows the general principles of treatment for any incomitant deviation in that the muscle(s) selected for manipulation must be the one(s) active in the field of largest deviation, especially when the primary position and downgaze (reading position) are concerned. One approach is to assume that the antagonist inferior oblique muscle always overacts to some degree and that weakening the inferior oblique muscle (recession, myectomy, myotomy) resolves up to approximately 15 PD of primary position hypertropia. Patients who have larger primary position hypertropias may require additional muscle surgery, usually a recession of the contralateral inferior rectus muscle (the yoke of the paretic superior oblique muscle) with or without an adjustable suture technique.

A comprehensive surgical management plan for this difficult problem was codified by Knapp<sup>73</sup> in 1974 and is summarized in [Box 11.9.1](#); it accounts for the observed spread of comitance and follows the general principles already outlined.

In classes 1 and 2, where only one gaze field has a large deviation, the muscle whose field of greatest action lies within that gaze field is operated

### BOX 11.9.1 Knapp's Classification of Superior Oblique Paresis

#### Class

1. Greatest deviation is with the affected eye elevated in adduction, the field of the ipsilateral (antagonist) inferior oblique muscle.
2. Greatest deviation is with the affected eye depressed in adduction, the field of the affected paretic superior oblique muscle.
3. Greatest deviation is in all contralateral gazes (down, level, and up).
4. Greatest deviations are in all contralateral gaze and in all downgaze positions (contralateral, straight, and ipsilateral).
5. Greatest deviations are in all downgaze positions.
6. V-pattern esotropia, cyclotropia, and bilaterally positive three-step test indicates a bilateral palsy.
7. Poor elevation and depression in adduction of the affected eye, resulting from direct injury to the superior oblique muscle, causing its restriction and paresis.

Adapted from Knapp P. Classification and treatment of superior oblique palsy. *Am Orthopt J* 1974;24:18–22.

on. The overacting inferior oblique muscle is weakened in class 1, and the paretic superior oblique muscle is strengthened with a tendon tuck or plication in class 2. A mild Brown's syndrome (inability to elevate the eye in adduction) is a desirable result following strengthening of the superior oblique muscle for class 2. However, superior oblique tendon tucks should only be performed when the tendon is sufficiently lax as determined by the intraoperative exaggerated forced duction test, otherwise a severe Brown's syndrome may result.

In class 3, where all contralateral fields are affected, inferior oblique muscle weakening or superior oblique muscle strengthening can be performed alone for vertical deviations below 20 PD; larger deviations may require adding a graded recession of the contralateral inferior rectus muscle. However, it should be mentioned that undercorrections in patients with large preoperative vertical fusional amplitudes are better tolerated than, and preferred over, overcorrections.

Class 4 cases evolve from class 3 cases—the deviation extends from the lateral gaze positions to affect all three downgaze positions as well. Knapp recommended the same treatment as in class 3 and then waiting for the downgaze deviation to resolve after the lateral gaze deviation had been treated, presuming that it was caused by temporary underaction of the ipsilateral inferior rectus muscle. If it did not resolve, he advocated resection of the inferior rectus muscle. More recent analysis attributes this pattern of deviation to contracture of the ipsilateral superior rectus muscle from constant long-standing hypertropia,<sup>49</sup> which may simulate contralateral superior oblique muscle overaction. Treatment requires recession of the ipsilateral superior rectus muscle if oblique surgery alone is insufficient.

Class 5 pareses have maximum deviations in the downgaze fields and are unusual. Although Knapp originally recommended tucking the affected superior oblique muscle in combination with tenotomy of the contralateral superior oblique muscle, this strategy may convert a unilateral palsy into a bilateral one.

Bilateral superior oblique muscle palsies constitute class 6; Knapp recommended bilateral tucking of the superior oblique tendon. In these cases, the predominant deviation is excyclotropia. Successful treatment has been accomplished with bilateral transposition of the anterior fibers of the superior oblique tendon, which are primarily responsible for its torsional action, as originally described by Harada and Ito<sup>74</sup> or more recently by the Fells modification.<sup>64,75</sup> Another option in mild cases is a bilateral nasal transposition of the inferior rectus muscles, which may be combined with a recession to treat a vertical deviation.<sup>76</sup>

Combined paresis and restriction of the superior oblique muscle constitute class 7 cases; these are usually caused by trauma, especially dog bites,<sup>73</sup> directly to the trochlear region. Surgery on the frontal sinus also can be responsible.<sup>15</sup> Knapp offered no solution for this difficult situation; initial alleviation of the restriction with subsequent treatment of the paretic component has since been recommended.

The vast majority of congenital cases have a demonstrable laxity or other abnormality of the tendon, which is infrequently found in acquired cases.<sup>77,78</sup> This can be assessed by intraoperative exaggerated traction test, and when present, it suggests treatment with a tendon-strengthening procedure, perhaps combined with weakening of the antagonist inferior oblique muscle.<sup>79</sup>

**SIXTH NERVE PALSY****Introduction**

Because only the lateral rectus muscle is affected, palsies of the sixth cranial nerve have presentations that are much less complex than those of the third or fourth cranial nerves. A deviation in the horizontal plane alone is produced, with no torsion or lid involvement, thus reducing the amblyogenic causes in susceptible children. Sixth nerve palsies are more common than either third or fourth nerve palsies in most age groups.<sup>21,45–48</sup>

**Epidemiology and Pathogenesis**

Congenital sixth nerve palsy is unusual and in many cases resolves rapidly.<sup>80</sup> If improvement is not forthcoming after serial observation, a neurological evaluation should be considered. More often, an esotropia with poor abduction of one or both eyes, dating from birth, represents another condition (Box 11.9.2), most commonly infantile esotropia. Children who have a large, constant esotropia often exhibit cross-fixation, fixating in the right field with their left eye, and vice versa, thus never having to abduct either eye. Sixth nerve palsy can be ruled out by provoking abduction, either by unilateral occlusion for a few hours or by utilizing the vestibulo-ocular reflex. The examiner holds the baby face to face at a close distance and spins around, first to one side and then to the other. If the reflex saccades in the opposite direction are brisk and the abduction full, sixth nerve palsy can be discounted. When abduction is truly limited, Duane's syndrome should be considered if there is narrowing of the palpebral fissure and eye globe retraction in adduction. Möbius' syndrome<sup>81</sup> is another possibility, although children with this disorder have other obvious problems (mask-like facies, poor feeding, hypoglossal atrophy, skeletal abnormalities) related to palsies of the seventh and twelfth cranial nerves in addition to the sixth cranial nerve. Congenital gaze palsy has also been reported<sup>82</sup> as a cause of an abduction deficit.

As it has a long intracranial course and the longest subarachnoid course of any cranial nerve, the sixth cranial nerve is prone to injuries from trauma and from nontraumatic diseases of contiguous structures, as summarized in Box 11.9.2. A benign ipsilateral recurrent palsy that follows a viral illness or immunization can affect children<sup>83,84</sup>; the adult counterpart has no known cause.<sup>85</sup> Studies indicate that in children, trauma, more than neoplasm, is a common cause of acquired sixth nerve palsy.<sup>21,45</sup> Earlier studies indicated the reverse, perhaps because of the delayed diagnosis of tumors prior to the advent of computed tomography (CT) and magnetic resonance imaging (MRI), a delay that allowed a paralytic strabismus to develop.<sup>45</sup> Acquired, bilateral palsies are more ominous than their unilateral counterpart.

Despite the lengthy list of possible causes, acquired unilateral sixth nerve weakness (Fig. 11.9.4) is often benign, even if recurrent.<sup>86</sup> However, careful examination must be performed to make sure the palsy is truly isolated and not accompanied by any other neurological findings suggesting a serious cause. Patients who have a truly isolated paresis may be initially observed with serial examinations.<sup>87</sup> However, further investigation

**Fig. 11.9.4 A 33-Year-Old Man With a Right Sixth Nerve Palsy.** (A) Right esotropia in primary position. (B) No deviation in contralateral (left) gaze. (C) Large esotropia in ipsilateral (right) gaze—the affected right eye cannot even get to midline position.

is indicated if no improvement occurs. Prompt, spontaneous resolution of sixth nerve palsy, however, does not rule out neoplasm as a cause in children or adults.<sup>88</sup> The appearance of new indicative findings or progression of the paresis demands immediate investigation. Although rare since the advent of antibiotics, children should be evaluated for otitis media as the cause. Gradenigo's syndrome occurs if contiguous inflammation of the petroclinoid ligament affects the adjacent sixth cranial nerve as it passes through Dorello's canal.<sup>89</sup>

**Ocular Manifestations**

Sixth nerve palsy manifests as esotropia, which almost always affects the primary position. The esotropia of a sixth nerve palsy initially exhibits the typical incomitance of a paralytic strabismus; the deviation is maximized in ipsilateral horizontal gaze and smallest in opposite gaze. In addition, the deviation is larger when the paretic eye is fixating (secondary deviation). However, contracture of its antagonist and yoke muscles (the ipsilateral medial rectus and the contralateral medial rectus muscles, respectively) can rapidly convert the deviation into a comitant esotropia.<sup>90</sup> In unilateral cases that have not yet developed comitance, an ipsilateral face turn may allow binocularity. In congenital palsies that result from Möbius' syndrome an esotropia may be lacking, and instead a gaze palsy may be present if the nucleus of the sixth cranial nerve is affected because the neurons that participate in horizontal conjugate gaze originate within the nucleus of the sixth cranial nerve.<sup>91,92</sup>

**Nonsurgical Treatment**

Surgical treatment of sixth nerve palsy should be deferred whenever a chance for improvement exists and at least for the first 6 months after

onset. During this period of expectant observation, young children who do not adopt the characteristic ipsilateral face turn to maintain binocularity should undergo unilateral occlusion to avoid the development of sensory adaptations. To minimize the possibility of amblyopia, the occlusion should alternate between the eyes. To minimize accommodation (which can worsen the esotropia), spectacles with full hypermetropic correction may be given. Adults also may appreciate unilateral occlusion to eliminate uncrossed diplopia.

Small deviations may be amenable to treatment with the use of prisms, especially because the originally incomitant deviation can rapidly become comitant because of contracture of both medial rectus muscles, as discussed earlier. To stimulate fusional divergence, the minimum amount of horizontal prism that allows fusion should be prescribed.

Chemodenervation with botulinum toxin can be used during the acute phase of sixth nerve palsy to prevent contracture of the antagonist medial rectus muscle while the lateral rectus muscle recovers function.<sup>17,18,93</sup> Despite its frequent lack of lasting benefit as a sole remedy for chronic palsy,<sup>18,19,93</sup> some patients may require or even prefer its repeated use as their treatment.<sup>94</sup> It is very useful as an adjunct to surgical management and sometimes essential to prevent or minimize the risk of postoperative ASI.

### Surgical Treatment

Surgical treatment should be considered when more than 6 months have passed after onset and serial examinations yield stable results. The goals of treatment are good ocular alignment in the primary position, expansion of the diplopia-free field, and improvement of the face turn. The surgical plan is largely determined by the depth of the palsy and the degree of medial rectus muscle contracture. Lateral rectus muscle function can be assessed directly by a force generation test,<sup>1</sup> careful observation of ipsilateral saccades, and modified electro-oculography.<sup>95</sup> Traditional forced duction testing estimates the degree of medial rectus contracture.

When at least some lateral rectus muscle function remains (usually with an esotropia of less than 30 D), a graded recess-resect procedure often succeeds; an undesired effect may, however, be an exotropia in the contralateral field of gaze. To avoid this situation, an alternative is a recess-resect procedure in the contralateral eye. Effective treatment when little or no abducting force remains generally requires a new source of abducting force provided by a muscle transposition procedure, together with weakening the antagonist medial rectus muscle, if contracted. Abducting force can be supplied by moving the adjacent vertical rectus muscles to the lateral rectus muscle insertion or by nonsurgical union of the adjacent halves of the lateral and vertical rectus muscles. The many variations of these techniques are reviewed elsewhere.<sup>96</sup>

The original Hummelsheim procedure<sup>97</sup> involves longitudinally splitting the superior and inferior rectus muscles and transposing each lateral half to the insertion of the paretic lateral rectus muscle. This procedure can be enhanced by resection of the transposed halves of the vertical rectus muscles.<sup>98,99</sup> Full-tendon transpositions (Fig. 11.9.5) can transfer more force, particularly if combined with a resection before reinsertion,<sup>100</sup> but have a higher risk of causing ASI. A proposed modification utilizes a posterior fixation suture to better direct the transferred force as horizontally as possible.<sup>101,102</sup> A muscle transposition of vertical recti without tenotomy and muscle splitting recently has been described<sup>103</sup> as a variation of the traditional Jensen procedure,<sup>104</sup> which entails longitudinal splitting of the lateral rectus and the vertical rectus muscles. The adjacent halves are then joined with a nonabsorbable suture, usually in conjunction with medial rectus muscle recession. Because the vertical recti are not severed from the globe, it was originally thought that this procedure would eliminate the risk of ASI, a theory that has since been disproved.<sup>105</sup> To minimize this risk and at the same time preserve the effectiveness of full-tendon transposition, adjunctive chemodenervation of the medial rectus muscle with botulinum

**Fig. 11.9.5** Full-tendon “transposition” of the superior and inferior rectus muscles to the insertion of the left lateral rectus muscle. (Courtesy R. Scott Foster, MD.)

toxin (instead of surgical recession) has been advocated<sup>106</sup> as has a lateral rectus plication along with Hummelsheim transposition (California Hummelsheim)<sup>107</sup> with or without medial rectus muscle weakening

### SUMMARY

In summary, the diagnosis and management of paralytic strabismus is complex. Patterns of incomitant strabismus must be analyzed using an array of tests and maneuvers to arrive at the correct diagnosis. Additional historical and physical findings must be sought to determine whether systemic evaluation is necessary. In spite of the multiple challenges encountered when surgically treating paralytic strabismus, results may be gratifying if surgical goals are clearly understood and surgical principles are followed.

## Other Vertical Strabismus Forms

11.10

Mitchell B. Strominger, Howard M. Eggers

**Definition:** Vertical strabismus not paretic in origin.**Key Features**

- Incomitance.
- Supranuclear or mechanical causation.

**INTRODUCTION**

The various findings in nonparetic vertical strabismus can be grouped into several clinical entities. All share incomitance as a feature. The causes are multiple and include supranuclear, strabismic, mechanical, restrictive, or muscle fibrosis.

**DISSOCIATED VERTICAL DIVERGENCE****Introduction**

Dissociated vertical divergence (or dissociated vertical deviation [DVD]) is characterized by a spontaneous upward deviation of either eye (dissociation) while the other eye fixates a target (Fig. 11.10.1).<sup>1</sup> The deviation is variable within an episode and from one dissociated episode to another. After a period of usually no more than a few tenths of a second or on a shift of gaze, the eye returns down and typically becomes transiently mildly hypotropic. The amplitude of the deviation and the frequency of spontaneous dissociation usually are not equal in the two eyes. The spontaneous deviation may occur with or without daydreaming or fatigue, although these states make the deviation worse or the spontaneous dissociation more common.

**Fig. 11.10.1 Dissociated Vertical Divergence.** (A) The eyes are approximately straight in primary position. (B) Occlusion of an eye leads to an upward drift of the covered eye. Dissociated vertical divergence is usually bilateral, although it may show asymmetrical amounts of drift. On cover testing, each eye drifts up when under cover. A measure of a simultaneous vertical deviation is the prism power that equalizes the amplitude of the vertical drift in the two eyes.

**Epidemiology and Pathogenesis**

Although DVD is most common with infantile esotropia, it can occur with any horizontal strabismus and sometimes as an isolated defect. Seldom present at birth, DVD frequently is a new finding after the age of 2–3 years and is thought to be associated with the early disruption of binocular development. Elevation in adduction, which produces an apparent inferior oblique muscle overaction, can be the initial presentation. Fusion maldevelopment syndrome (FMS; latent or manifest latent nystagmus) commonly occurs with DVD in infantile esotropia.

**Ocular Manifestations**

In cover testing, the eye drifts upward, outward, and excyclorotates behind the occluder. The eye then returns downward when the occluder is removed and fixation restored. The uncovered eye typically remains stationary. Binocular visual input thus plays a role in stabilization of the eyes in the primary position, although the deviation can occur with inattention, or be manifest. Because the deviated eye usually is suppressed, diplopic symptoms seldom occur.<sup>2</sup> Rarely, the suppression is not deep enough, and vertical diplopia occurs. Occasionally, a patient may find it physically uncomfortable for the eye to turn upward. The spontaneous deviation may also disturb psychosocial function.

Because each eye drifts upward under cover and moves downward on removal of the cover, it is difficult to measure accurately the vertical deviation of DVD. Thus, the prism power that makes the residual vertical drift symmetrical can be used as an estimate. Occasionally, the drift movement is chiefly horizontal and the term *dissociated horizontal deviation* is used.<sup>3</sup> If it is primarily torsional, the term *dissociated torsional deviation* is used.

**Diagnosis**

The cause of DVD is the subject of much speculation. The normal versions and ductions imply a defect in supranuclear control of eye position. Eye movement studies implicate an abnormal vertical vergence system.<sup>4</sup> The Bielschowsky phenomenon is a curious characteristic of DVD that must be related to the abnormal supranuclear control of vertical eye position. It is demonstrated by occlusion of one eye to make it deviate upward. Then, a neutral density wedge is placed before the opposite, unoccluded eye. The eye behind the cover makes a gradual downward movement in proportion to the attenuation of light that reaches the open eye. This phenomenon sometimes becomes manifest in a blind or significantly visually impaired eye.

**Differential Diagnosis**

The characteristic findings in DVD eliminate the need for any differential diagnosis except in cases that have minimal involvement, concurrent vertical deviation, or difficulty in examination because of the patient's young age. Overaction of the inferior oblique (primary or secondary) muscle and superior oblique muscle paresis must be ruled out. In cases of vertical strabismus, a coexisting DVD may be difficult to diagnose.

**Treatment**

Although binocular sensory and motor fusional capacity is poor in DVD, the aim of nonsurgical therapy for DVD is to strengthen the patient's fusional mechanisms. This is done by elimination of any concurrent strabismus, and optimization of vision through accurate refractive prescription and treatment of amblyopia. Indications for surgery are visual symptoms, physical discomfort from a large deviation, or disfigurement produced by

the updrift. A variety of surgical procedures have been advocated for DVD. These include resection of the inferior recti, recession of the superior recti with or without a Faden (posterior fixation) procedure, and anterior transposition of the inferior oblique.<sup>5-8</sup> If one eye is used habitually for fixation, surgery needs to be performed only on the opposite eye. If either eye is used at times for fixation, both eyes need to be operated on, but asymmetrically, each eye in proportion to its drift. Dissociated horizontal deviation can be corrected by lateral rectus recession on the involved side.

## PRIMARY INFERIOR OBLIQUE MUSCLE OVERACTION

### Epidemiology and Pathogenesis

Overelevation in adduction may be the result of primary overaction of the inferior oblique muscles. The cause is unknown, although it is associated with horizontal strabismus. An anatomical variation plays a role because it can be seen in craniosynostosis. A difference in the plane of action of the superior and inferior oblique muscles, referred to as *desagittalization*, may leave the inferior oblique with a stronger vertical action in adduction than the superior oblique muscle.<sup>9</sup> Excyclorotation of the globe or orbit may raise the insertion of the medial rectus above the horizontal midline to give it a vertical action that assists elevation in adduction and simulates inferior oblique muscle overaction.

### Ocular Manifestations

Primary inferior oblique muscle overaction refers to a marked elevation of an eye when in the adducted position under binocular viewing conditions (Fig. 11.10.2). Usually, no vertical deviation occurs in primary position. When bilateral, a right hypertropia is seen in left gaze and a left hypertropia in right gaze. The elevation in adduction may be bilaterally symmetrical or asymmetrical. The head-tilt test result is negative and depression

on adduction is normal. It is typically associated with a horizontal strabismus, either an esotropia or exotropia, and produces a V-pattern (see Chapter 11.8).

### Differential Diagnosis

The differential diagnosis includes secondary inferior oblique muscle overaction (from a paretic ipsilateral superior oblique or contralateral superior rectus muscle), Duane's syndrome, and DVD. Overaction secondary to superior oblique muscle paresis shows a positive head-tilt test. The differentiation of DVD from inferior oblique muscle overaction is important as it dictates the surgical options.

Primary inferior oblique muscle overaction commonly occurs in infantile esotropia and is frequently confused with DVD. Genuine inferior oblique muscle overaction should produce a V pattern and show measurable vertical deviations in lateral gaze. The abducted eye becomes lower as the high, adducted eye takes up fixation. The deviation is the same regardless of which eye fixates.

In DVD, dissociation of the eyes occurs by occlusion of much of the visual field of the adducted eye by the nose and eyebrow, which results in elevation of the occluded eye. If the adducted eye is the fixating eye, much less or no elevation occurs in adduction. Occlusion of the abducted eye may make that eye elevate and thus reverse the hypertropia findings. The updrift and recovery movements are slower than in a true tropia of inferior oblique muscle overaction and are frequently accompanied by torsional movements, excyclotorsion as the eye rises, and incyclotorsion during recovery.

### Treatment

When elevation in adduction genuinely results from inferior oblique muscle overaction, a weakening procedure is required for these muscles.<sup>10</sup> Surgical options include inferior oblique muscle recession, myotomy, or myectomy. If a concurrent DVD is present, inferior oblique muscle anterior transposition may reduce the upward drift. Apparent overaction of the inferior oblique muscles may disappear after surgery for esotropia.

## MONOCULAR ELEVATION DEFICIENCY (PREVIOUSLY TERMED "DOUBLE ELEVATOR PALSY")

### Introduction

Monocular elevation deficiency (MED) is an apparent paralysis of both elevators (superior rectus and inferior oblique muscles) of one eye that results in a hypotropia on the affected side that increases on upgaze. The levator palpebrae may or may not be involved. A subtype with inferior rectus muscle restriction may occur. Bell's phenomenon is usually absent but, if present, implies a supranuclear lesion. The pupil is normal, as are horizontal rotations.

### Epidemiology and Pathogenesis

MED may be congenital or acquired. The cause of the congenital form is not known. Acquired cases have all been adults who have small lesions in the pretectum, thus necessitating neuroimaging.<sup>11</sup>

### Differential Diagnosis

The differential diagnosis includes mechanical restriction of elevation (orbital floor fracture, thyroid orbitopathy, congenital fibrosis of the extraocular muscles) and Brown's syndrome (which can sometimes affect primary position).

### Treatment, Course, and Outcome

Forced ductions should be carried out to confirm any mechanical restriction. Surgical treatment traditionally consists of transferring the entire tendon of both the medial and lateral rectus muscles to the superior rectus muscle insertion (Knapp's procedure).<sup>12</sup> Horizontal rotations are impaired only slightly, and vertical rotations are improved remarkably. If the inferior rectus is restricted, it has to be recessed, which can be done in a stepwise, staged-surgery approach evaluating alignment and the need for a second surgery after healing has occurred. Because four anterior ciliary arteries

**Fig. 11.10.2 Elevation in Adduction.** The apparent overaction of the inferior oblique muscle must be confirmed with cover testing. A dissociated vertical divergence frequently gives the same appearance on testing versions. True inferior oblique muscle overaction gives a measurable deviation in lateral gaze and may produce a V-pattern. In dissociated vertical divergence, the abducted eye may circumduct under occlusion. (A) Right gaze. (B) Gaze in primary position. (C) Left gaze. Note elevation of adducted eye in lateral gaze to either side.

are sacrificed for the transposition, it is best to allow 6 months for adaptation of the blood supply before operation on a third rectus muscle. Alternatively, dissection and preservation of the anterior ciliary arteries from the muscle may enable the third muscle to be included at the initial operation. If the lid height does not improve with the raising of eye position, lid surgery may be needed.

## BROWN'S SYNDROME

### Introduction

The motility features of the superior oblique tendon sheath syndrome were originally thought to result from a short anterior sheath of the superior oblique tendon but now are attributed to various abnormalities of the tendon–trochlea complex (Fig. 11.10.3).<sup>13</sup>

### Epidemiology and Pathogenesis

In Brown's original series, there was a 3:2 predominance of women to men and nearly twice as many cases involved the right eye as the left; 10% of cases showed bilaterality. Familial occurrence of Brown's syndrome has been reported.<sup>14</sup>

### Ocular Manifestations

The most striking clinical feature is restriction of elevation in adduction, which is limited to the horizontal plane. The lid fissure may widen when the eye is adducted. Because the limitation arises from mechanical factors, it is the same on version, duction, and forced duction testing. The maximal elevation can increase as the eye moves from adduction to abduction, in which it is normal. Divergence in upgaze from primary position is seen, but normal elevation occurs into supra-abduction (normal superior rectus muscle function), thus differentiating it from MED. The ipsilateral superior oblique muscle usually does not overact. Variable features are head tilt and tropia in all fields. Some acquired and congenital cases have been noted to resolve spontaneously.

Acquired cases arise from orbital trauma,<sup>15</sup> direct trochlear trauma, orbit or muscle surgery, scleral buckling, frontal sinusitis or sinus surgery, Molteno valve implantation, and inflammation of the superior oblique tendon or sheath. Orbital floor fractures may trap the orbital tissue in such a way as to simulate Brown's syndrome. Brown's syndrome is produced easily during surgery to tuck the superior oblique muscle if the tendon sheath is not stripped away adequately or if the surgery is carried out too close to the trochlea. Inflammation of the superior oblique tendon has occurred in rheumatoid arthritis and juvenile rheumatoid arthritis.<sup>16–18</sup> Intermittent forms of vertical retraction syndrome have been associated with a click, which occurs as the restriction is released (superior oblique click syndrome).<sup>19,20</sup>

### Treatment

If binocular vision is present and the head position is correct, treatment is not obligatory. Treatment is required for visual symptoms, strabismus, or incorrect head position. Acquired cases that have active inflammation of the superior oblique tendon may benefit from local corticosteroid injections in the region of the trochlea.<sup>16</sup> Prisms may provide some relief from diplopia in acquired forms.

The goal of surgery is to restore free ocular rotations. Intraoperative aggressive forced ductions can improve movement in some of cases but the majority requires a surgical procedure. Brown advocated that the superior oblique tendon be stripped. The results of such a procedure often are unsatisfactory because of reformation of scar tissue. A procedure of luxation of the whole trochlea, with the superior oblique tendon and orbital structures left intact, appears promising.<sup>21</sup> Tenotomy of the superior oblique tendon also can be performed.<sup>22</sup> This has the disadvantage that it frequently produces a superior oblique muscle paresis.<sup>23</sup> Furthermore, if the tendon is not tight, the tenotomy may not improve the restricted movement. Currently, insertion of an inert spacer or suture between the cut ends of the superior oblique tendon is advocated. During surgery, a traction test is repeated frequently until the globe rotations are free.

## CONGENITAL FIBROSIS

Congenital fibrosis of the extraocular muscles (CFEOM) is a group of conditions within the general category of the congenital cranial disinnervation

**Fig. 11.10.3 Brown's Syndrome.** Elevation of the left eye is impaired most in right gaze. The differential diagnosis includes inferior rectus muscle paresis. Brown's syndrome is characterized by a positive traction test for elevation in adduction, but muscle paresis is not. (A) Gaze to right and up. Note limitation of elevation of adducted left eye. (B) Gazing upward shows mild limitation of elevation of left eye. (C) Gazing left and up shows no restrictions. (D) Gazing to the right shows no vertical deviation in this case, but one may be present with additional testing. (E) Primary position shows no deviation.

disorders<sup>24</sup> (CFEOM1, CFEOM2, CFEOM3, and Tugel's syndrome). It manifests as a variable degree of fibrosis and atrophy of the extraocular muscles innervated by the third and fourth cranial nerves. This leads to a restrictive orbitopathy. Blepharoptosis and a compensatory elevated chin position occur. Attempts at upward eye movements may result in convergence. The overall prevalence is 1:230 000 and has been identified throughout the world. Tugel's syndrome is associated with hand anomalies. The differential diagnosis includes Graves' disease, Brown's syndrome, orbital floor fracture, monocular elevation deficiency, and chronic progressive external ophthalmoplegia.

Surgical treatment can relieve the extreme downward tethering of the eyes. The head position improves as a result. The lids may need to be

raised, but caution is necessary because the upward rotation of the eyes is limited and the normal Bell's phenomenon does not occur with blinking. It, therefore, is easy to produce corneal exposure with eyelid raising procedures.

## FRACTURES OF THE ORBITAL FLOOR

### Ocular Manifestations

Ocular motility may be impaired in orbital floor fractures as a result of proptosis and edema from the original trauma, muscle contusion, intraorbital hemorrhage, herniation of the orbital fascia, and muscle entrapment.<sup>25</sup> Eye movements in general, but particularly elevation and depression, may be limited. The inferior rectus is the muscle most commonly affected.

### Diagnosis

The diagnosis of inferior rectus entrapment is made on the basis of the presence of limited elevation on the affected side, which results in hypotropia, and a positive forced duction testing. Mild cases show hypotropia only in upgaze. Depression may be limited by entrapment or by damage to the nerve to the inferior rectus muscle. Because of the oculocardiac reflex, attempted upgaze in cases of inferior rectus entrapment may be accompanied by bradycardia, especially in the pediatric population. Diplopia may persist after the inferior rectus muscle has been freed.

The pathophysiology of any resultant strabismus is the herniation of the orbital contents—fat, connective tissue septa, and muscle—into the fracture and consequent tethering of the eye. If the entrapment is old, the muscle can become permanently fibrotic and inelastic, which results in a reduced range of rotation. A paresis of the inferior rectus also may occur, which presumably arises from trauma to the nerve that supplies the inferior rectus. On occasion, the inferior rectus muscle may be devitalized by compromise of its blood supply. The muscle is then found to be quite friable at the time of surgery.

### Treatment

A floor fracture does not require repair if no disturbance of motility exists.<sup>25</sup> Large fractures, however, should be repaired to prevent enophthalmos. Some clinicians treat immediately while others wait for up to 2 weeks for regression of the edema. Unfortunately, fracture repair may not free the inferior rectus muscle adequately, necessitating ocular muscle surgery for the hypotropia that remains with restriction to elevation.

## GRAVES' OPTHALMOPATHY (DYSTHYROID ORBITOPATHY)

### Introduction

Dysthyroid orbitopathy is an autoimmune inflammatory condition that involves the orbital tissues, primarily the muscles and fat, but spares the muscle tendons. The muscles are affected by an autoimmune inflammatory process of interstitial edema and round cell infiltration. The muscles enlarge and then become fibrotic and inelastic. Other findings are lid edema, proptosis, lid retraction, and compressive optic neuropathy. Proptosis results from edema and enlargement of the muscles and orbital fat.

### Ocular Manifestations

The usual motility findings are caused by a restrictive myopathy. In addition, orbital inflammation can result in diffuse adhesions of Tenon's capsule and orbital tissues to the globe. The inferior rectus muscle is the most commonly affected, resulting in limitation of elevation. When the condition is more severe, the eye may be tethered down by the inferior rectus muscle leading to a hypotropia in the primary position. The medial rectus muscle is the next most commonly involved, followed by the superior and lateral recti ( $I > M > S > L$ ). The oblique muscles also may be involved, although rarely. The orbitopathy frequently is asymmetrical between the two eyes.

## Diagnosis

The diagnosis is primarily clinical because the patient may have any level of thyroid activity. Thyroid ophthalmopathy also may recur after many quiescent years. Orbital computed tomography (CT), magnetic resonance imaging (MRI), or B-scan ultrasonography shows enlargement of the muscles with tendon sparing. Forced duction testing demonstrates restriction. Intraocular pressure becomes elevated as the eye attempts to rotate against the restriction. Usually, lid edema, proptosis, or lid retraction is present in addition to any motility disturbance.

### Treatment

Treatment of dysthyroid orbitopathy begins with correction of the thyroid state by an endocrinologist. The goal from the ophthalmic standpoint is single vision in the primary position and downgaze. Fresnel press-on prisms and/or botulinum toxin injections may provide some relief of diplopia until the deviation has stabilized. Because more than one muscle usually is involved, horizontal, vertical, and occasionally oblique deviations are present, the patient should be observed until the deviation has stabilized and the orbital inflammation has subsided. This often may take 6 months or longer. Although some improvement in motility may occur as a result of subsidence of orbital edema, the fibrotic changes in the muscles prevent resolution of the portion of the deviation that arises from restrictive muscle changes. Surgically, tight muscles are recessed to enable better movement and reduce the deviation. A secondary goal is to improve the incomitance. An untoward effect of recessing a restrictive muscle, however, is to produce an underaction in its field of action, thus potentially producing diplopia in an area not seen previously. This is especially true when recession of a tight inferior rectus muscle may produce worse diplopia in a downward reading position. Finally, resection of a fibrosed muscle may worsen the deviation and is reserved for special circumstances and then only limited to the tendon and not the infiltrated muscle belly.

## HEAVY EYE SYNDROME

Convergent strabismus fixus ("heavy eye syndrome") is an ocular motor abnormality, in which the eye is fixed in adduction. It usually also is hypotropic with limitation of elevation. Typically associated with moderate to high myopia, it is a progressive disorder that can initially mimic a paralytic strabismus but then becomes restrictive. Orbital imaging studies demonstrate a slippage or displacement of the extraocular muscle path and pulley, with the lateral rectus muscle displaced inferiorly and the superior rectus muscle displaced medially. Loop myopexy, with or without medial rectus muscle weakening, has become the treatment of choice for this disorder.<sup>26</sup>

# Amblyopia

George S. Ellis, Jr., Cindy Pritchard

# 11.11

**Definition:** Amblyopia is a developmental defect of spatial visual processing that occurs in the central visual pathways of the eye.

## Key Features

- Decreased recognition associated with decreased vernier (determining offset) and grating acuity (distinguishing contrasted grating stripes).
- Accentuation of the “crowding” phenomenon.
- Unsteady fixation.

## Associated Features

- Decreased contrast sensitivity and spatial localization.
- Abnormal accommodation.

## Experimental Findings

- Receptive fields larger than normal.
- Functionally better under scotopic and mesopic conditions than under photopic conditions.
- Reduced reaction time.

## INTRODUCTION

Amblyopia is a “developmental defect of spatial visual processing that occurs in the central visual pathways of the brain.”<sup>1</sup> In essence, it presents as loss of visual acuity in one or, occasionally, both eyes. Amblyopia most often occurs in otherwise healthy eyes but can be an added cause of poor vision in eyes with other ocular pathology. The neurodevelopmental defects associated with amblyopia are a result of lack of use of one or both eyes or a result of a long-standing defocused image. Fortunately, the neuroplasticity that allows amblyopia to develop also permits successful treatment if the amblyopia is detected and treated early enough in the critical period of development of the visual system. Early detection is imperative for successful treatment. Therefore, clinicians must have a clear understanding of amblyopia and its clinical associations, detection strategies in infants and young children, and the armamentarium of treatment approaches. Only then is restoration of visual acuity possible in an eye with amblyopia.

## CLASSIFICATION OF AMBLYOPIA (THE THREE DS)

### Strabismic Amblyopia (Deviated Image)

Amblyopia can develop in children with manifest strabismus, with these children habitually fixating with one eye and suppressing use of the fellow eye. No correlation exists between the size of deviation and the depth of amblyopia.<sup>2</sup> Therefore, amblyopia is a concern even in the presence of very small heterotropia. Children with intermittent strabismus are less susceptible to amblyopia, but the risk is still present.<sup>3</sup>

### Anisometropic Amblyopia (Defocused Image)

Children with uncorrected anisometropia can become amblyopic. The diagnosis is made when the decreased acuity in the more ametropic eye

does not immediately improve and become normal with use of corrective lenses. This acuity loss extends to the peripheral visual field equally nasally and temporally, which implies uniform degradation of the visual system in an amount proportional to the anisometropia.<sup>4</sup> As monocular visual function in the far temporal periphery of the visual field is spared, the acuity defect found in the more central field must result, in some part, from abnormal binocular interaction.<sup>5</sup>

A study by Donahue demonstrated that the prevalence of amblyopia in very young children with anisometropia is low; however, the prevalence and depth of amblyopia increases with age.<sup>6</sup> This suggests that spectacle correction of anisometropia in the absence of amblyopia might prevent later development of amblyopia. Depth of amblyopia correlates with the degree of anisometropia.<sup>7</sup> The risk of developing amblyopia is greatest when the hyperopic refractive errors between the two eyes differ by more than about 2.00 D, when the myopic refractive errors differ by more than about 4.00 D, or when astigmatic errors differ by more than about 1.25 D.<sup>6</sup> Patients who have anisometropic hyperopia exert sufficient accommodation to provide clear visual acuity in the less hyperopic eye, leaving the other eye blurred and at risk for development of amblyopia. Essentially, with sufficient anisometropia, children will automatically choose to use the clearer (less ametropic) eye for fixation, ignoring the blurred fellow eye. For children with monocular astigmatism, the amblyopia may be confined to a meridian in which maximal defocusing occurs. This type of amblyopia, referred to as “meridional” amblyopia, has been documented in reports of experimental studies.<sup>8</sup>

## Stimulus-Deprivation Amblyopia (Deprived Image)

Any congenital or early acquired condition that results in an obscuration of the visual axis in one or both eyes can lead to stimulus-deprivation amblyopia. If the condition is left untreated, the amblyopia that develops may be devastating visually and sometimes irreversible. Common causes include cataract, corneal opacity, pupil anomalies, severe ptosis, and lid masses (Fig. 11.11.1). Another form of stimulus-deprivation amblyopia is that associated with long-standing bilateral uncorrected high refractive errors. This is commonly referred to as “refractive amblyopia” and is most often seen with bilateral high hyperopia or bilateral high myopia but can occur with bilateral high astigmatism as well. In such cases, both eyes are amblyopic. The diagnosis is made when, in the absence of other eye disease, visual

**Fig. 11.11.1 Stimulus-Deprivation Amblyopia.** A 6-month-old infant with infantile hemangioma of the right upper lid, completely covering the visual axis.

acuity bilaterally is subnormal when the appropriate refractive correction is in place.

## PATHOPHYSIOLOGY

During visual development, in a period known as the *critical period*, the anatomy and physiology of the visual system are malleable. Animal experiments have provided useful insights into the physiological and anatomical processes that occur in humans. Hubel and Weisel were the first to investigate the neuroanatomical and neurophysiological effects of monocular deprivation, which eventually led to their being awarded the Nobel Prize for Physiology/Medicine in 1981. Their early studies involving monocularly deprived kittens demonstrated a reduction or shrinkage in cells responsive to stimulation of the deprived eye in the visual cortex and lateral geniculate body.<sup>9,10</sup> Projections from the lateral geniculate nucleus to the visual cortex are similarly affected. Cortical stripes from the affected eye are narrower than normal, and stripes from the sound eye wider than normal.<sup>11</sup> The effects of monocular deprivation reflect competition from the open eye as well as loss of connections with the deprived eye. Ocular dominance histograms demonstrate the changes that occur in the visual cortex (Fig. 11.11.2).<sup>12</sup> Further investigation in amblyopic monkeys demonstrated that these changes can be reversed by suturing the lid of the sound eye.<sup>13</sup> Using kittens as a model for exploring the critical period, a study showed that monocular deprivation brought on by lid closure is most devastating between 4 and 6 weeks of age, during which time 3 days of monocular closure results in most cortical cells being driven by the open eye. Susceptibility decreases from age 6 weeks to age 3 months; some susceptibility persists until age 9 months.<sup>14</sup> In addition to changes in the visual cortex and lateral geniculate body, other area of the brain have been shown to be involved in amblyopia. Diffusion tensor imaging has detected changes in the anterior visual pathways of subjects with amblyopia.<sup>15</sup> Abnormalities in the structural properties of major white matter tracts in strabismic amblyopia have been described.<sup>16</sup> In animal models with stimulus deprivation amblyopia, arbors of fine-detail cells (X cells) in the geniculate were found to be larger than normal, and arbors of movement cells (Y cells) were smaller than normal.<sup>17</sup> Evidence of retinal involvement has been reported as well, for example, abnormalities of electro-oculography implicating the pigment epithelium.<sup>18</sup> Choroidal thickening in anisometropic and strabismic amblyopia has been demonstrated in studies utilizing optical coherence tomography (OCT).<sup>19</sup>

Many studies have reported functional defects in the visual system of amblyopia in animals and humans. Although it is beyond the scope of this chapter to report all of the findings, some are especially noteworthy to exemplify the abnormal quality of vision associated with amblyopia. Some of the abnormalities can be found in one of the classifications of amblyopia (strabismic, anisometropic, etc.) but not in another classification. For example, vernier acuity is about six times more precise than grating or optotype acuity in normal eyes and in eyes with anisometropic amblyopia

but is less precise in eyes with strabismic amblyopia.<sup>20</sup> This degradation of vernier acuity occurs at both fine and coarse levels. Contrast sensitivity in eyes with strabismic amblyopia may be normal or abnormal at high spatial frequencies. However, for anisometropic amblyopic eyes, the contrast sensitivity curve shows substantial losses at high spatial frequencies only (Fig. 11.11.3).<sup>21,22</sup> Spatial localization as measured by Hess and Holliday is decreased in proportion to contrast sensitivity loss (Fig. 11.11.4).<sup>22</sup> Additional abnormalities include abnormal accommodation and reaction times. Studies have shown that when accommodation is tested in subjects with amblyopia, a reduction occurs in the slope of the stimulus/response curve for the amblyopic eye.<sup>23</sup> Amblyopic eyes also have delays in reaction time that correlates with the decrease in visual acuity.<sup>24</sup>

**Fig. 11.11.2 Ocular Dominance Histograms.** Normal area 17 depicts a normal monkey and is derived from 1256 recordings of visual cortex cells in monkeys of all ages. Monocular closure is from a monocularly deprived monkey (the right eye was occluded from 2 weeks to 18 months of age; recordings were taken from the left hemisphere). Each cell is driven solely by the ipsilateral eye (group 7), contralateral eye (group 1), both eyes (group 4), or somewhere in between (groups 2, 3, 5, and 6). (Data from Hubel DH, Weisel TN, LeVay S. Functional architecture of area 17 in normal and monocularly deprived macaque monkeys. Cold Spring Harbor Symp Quant Biol 1975;40:581–9.)

**Fig. 11.11.3 Contrast sensitivity for those with hyperopic and myopic anisometropia in binocular and monocular visual fields.** Red lines represent the amblyopic eye, blue lines the sound eye, and purple the monocular visual field. (Data from Hess RF, Pointer JS. Differences in the neural basis of human amblyopia: the distribution of the anomaly across the visual field. Vision Res 1985;25:1577–94.)

## SPATIAL LOCALIZATION TEST

**Fig. 11.11.4 Spatial Localization Test.** The goal of this test is to align the middle grating between the upper and lower gratings.

## DIAGNOSIS

The diagnosis of amblyopia should be considered whenever subnormal acuity cannot be explained by physical findings, particularly in the presence of an amblyogenic condition (strabismus, anisometropia, bilateral high refractive error, or obstruction of visual axis). It is important to recognize that in children with strabismus, even a very small deviation of the visual axes can lead to amblyopia. Because amblyopia cannot be diagnosed solely on the basis of the results of physical examination of the eye and because it can be present when all ocular structures are normal, it is important to carefully assess the visual function for each eye in children in the amblyogenic age group.

A feature of amblyopia of any type is accentuation of the “crowding” phenomenon or spatial interference effect, in which single optotypes are discerned more easily than those in a larger array.<sup>25</sup> Thus, for verbal children, in whom acuity can be determined with Snellen letters or preliterate figures, the presence of crowding difficulty can help confirm the diagnosis. When single-letter or single-picture acuity is better than linear acuity, it is suggestive of amblyopia. Some vision charts allow for the use of “crowding bars” that can simulate linear presentation when isolated optotypes are used for testing. These bars surround the isolated figure or letter resulting in an acuity that is more consistent with linear acuity. Another characteristic of amblyopic vision involves the impact of illumination on acuity. The acuity of amblyopic eyes is better under scotopic or mesopic conditions than under photopic conditions.<sup>26</sup> If a neutral-density filter is available, acuity will remain the same or, in some cases, improve slightly when viewing through the filter with an amblyopic eye. In a normal healthy eye, the acuity will be slightly reduced through the filter. In the presence of organic disease, the neutral-density filter will cause a dramatic reduction in acuity.<sup>26,27</sup>

Determining whether or not amblyopia is present is much more challenging with preverbal infants and with nonverbal developmentally delayed older children. In such cases, acuity can be evaluated by behavior with monocular occlusion. For example, if a child does not object to occlusion of the right eye but rejects occlusion of the left eye (i.e., by moving away from the cover or by crying consistently, etc.), it can be assumed that the right eye has decreased acuity. In addition, the ability to fix and “follow” a small target with each eye can be compared and fixation evaluated with regard to two parameters: central versus eccentric fixation and steady versus unsteady fixation. Amblyopia can be associated with eccentric fixation (Fig. 11.11.5). Patients with eccentric fixation no longer fixate with their fovea, using nonfoveal points to fixate. Unsteady fixation can occur both with central and eccentric fixation and indicates amblyopia in that eye. Therefore, evaluating fixation as central or eccentric and steady or unsteady can assist in assessment for amblyopia when a subjective measurement of acuity is not possible. Another useful tool for assessing visual function when subjective measures cannot be obtained is evaluating maintenance of fixation preference in children who have manifest or induced strabismus. Alternating fixation implies equal acuity in each eye. If a child prefers fixation with one eye, determining the strength of the preference adds valuable information. The poorer the vision in the nonpreferred eye,

**Fig. 11.11.5 Diagnosis of Eccentric Fixation.** A target is projected onto the retina using a special ophthalmoscope. The observer examines where the fixation target falls on the retina relative to the fovea. The marks indicate the locations of successive fixations in a case of eccentric fixation. In general, the poorer the vision, the greater is the scatter and the greater is the distance from the fovea.

**Fig. 11.11.6** A 20 $\Delta$  base down prism test showing no preference for fixation with one eye suggesting equal vision. (A) Vertical prism is placed in front of right eye. Corneal light reflex shows that child is fixating with left eye. (B) Vertical prism is placed in front of left eye. Corneal light reflex shows that child is fixating with right eye.

the shorter the period the child will maintain fixation with the nonpreferred eye under binocular conditions. This test is performed by covering the dominant eye and forcing the child to fixate on an interesting target with the nonpreferred eye. When the cover is removed, the examiner watches to see how long the child will continue to maintain fixation with the non-dominant eye. The clinician assesses whether fixation is held through a blink-to-blink period, for a few seconds only, or momentarily before fixation is switched back to the dominant eye. Although this manner of vision testing can yield false-positive and false-negative results for amblyopia, it is widely accepted by clinicians for vision assessment in preverbal infants and children with strabismus.<sup>28</sup> Visual function can be tested in a similar manner in children without strabismus by optically inducing a vertical or horizontal deviation with a 10 $\Delta$ –20 $\Delta$  vertical or horizontal prism placed in front of one eye (Fig. 11.11.6).<sup>29</sup>

A mild afferent pupillary defect may be seen in the presence of amblyopia; this, however, implies an organic cause for decreased visual acuity.<sup>29,30</sup> It is important to keep in mind that amblyopia can occur along with ocular pathology. For example, with unilateral optic nerve hypoplasia, the acuity

**Fig. 11.11.7 Grating Acuity Thresholds versus Crowded Snellen Acuity Thresholds.** Snellen acuity is affected much more than grating acuity in strabismic amblyopia.

of the affected eye will be reduced as a result of the abnormal optic nerve. The acuity can become further degraded with superimposed amblyopia. Many clinicians treat these children for amblyopia to achieve acuity that meets the maximum potential of the involved eye.

Forced-choice preferential looking techniques (e.g., Teller acuity cards) are used by some clinicians to assess acuity in infants and preverbal children. It is important to be aware that acuity in amblyopic eyes is overestimated by grating techniques (Fig. 11.11.7).<sup>31</sup> Therefore, tests for visual acuity, such as Teller acuity cards, may be useful in the detection of moderate or severe amblyopia but may fail to detect mild amblyopia.<sup>32</sup>

## TREATMENT

Since plasticity of the visual system diminishes with age, early treatment is essential for optimal outcomes. It is important to recognize, however, that older children also can benefit from amblyopia treatment. Numerous studies describe successful improvement of visual acuity in strabismic or anisometropic amblyopia in teenagers.<sup>33</sup> In addition, patients who have abnormal structural lesions may have a superimposed amblyopia. Many patients who have abnormal structural eye lesions benefit from a trial of amblyopia therapy.<sup>34</sup>

Correction of anisometropia and significant refractive errors is an essential preparation for active amblyopia treatment. As many with amblyopia have deficient accommodation, hyperopic refraction often needs to be corrected.<sup>23</sup> Keratorefractive surgery has been performed for high degrees of anisometropic amblyopia; this treatment, however, usually is resorted to when conventional amblyopia treatment has failed.<sup>35</sup>

It is not always necessary to remove cataracts prior to amblyopia therapy. If the cataract is small or diffuse, amblyopia therapy can be initiated prior to lens extraction. The benefit of an intact natural lens with its accommodative abilities can outweigh the benefit of a perfectly clear visual axis. If, with adequate amblyopia treatment, the vision does not reach an acceptable level, cataract extraction can then be considered.

## Occlusion

Occlusion of the sound eye has long been recognized as an effective treatment for amblyopia. The most common type of occlusion is an adhesive patch (Fig. 11.11.8). Adhesive patches can, however, cause skin irritation. This can sometimes be minimized by changing to another brand with a different adhesive or varying the size of the patch so that the adhesive contacts a different area of skin. Junior-size patches often can provide adequate occlusion even in older children. Another approach to minimizing skin irritation is to create a barrier between skin and the adhesive by using tincture of benzoin or milk of magnesia. Milk of magnesia will leave a residual fine powder on skin when it dries. The patch can then be applied with the powder acting as a barrier. Parents should be forewarned that the child will likely resist the patch. Pirate-style patches are not recommended because they are easily removed, and peeking is easy (Fig. 11.11.9). Emphasizing the importance of adequate treatment will strengthen the parents' resolve when they are confronted with resistance from the child.

**Fig. 11.11.8 Adhesive Patches.** Decorative patches (left) are commercially available online. Flesh tone patches (right) are available at many stores. To make patching more fun, the child and his classmates can decorate the flesh tone patches with stickers or with drawings.

Some clinicians recommend arm restraints when all attempts for adequate patching fail. Arm restraints are commercially available, however, "floaties" for the pool secured with tape at the elbow can be useful in preventing the child from bending his arm to reach the patch for removal.

Glasses fit well over adhesive patches. When glasses are worn, however, nonadhesive patches can be utilized. Most varieties are made with heavy felt that prevents light from passing through the patch. The disadvantages of nonadhesive patches are that they are easily removed by simply removing the glasses and the child can easily peek over the patch by sliding the glasses down the nose to view over the top of the patch.

Patients who undergo full-time occlusion are re-evaluated at intervals of a week per year of life to a maximum of 4 weeks; thus, a 6-month-old child returns in 3 days, and a 4-year-old should return in 4 weeks. Part-time occlusion can be effective and safely allows longer intervals between follow-up visits.<sup>36,37</sup> Furthermore, it has been known for at least 70 years that part-time patching reduces the risk of development of occlusion esotropia, which can occur in children with no strabismus prior to patch treatment.<sup>38</sup>

When peeking over the glasses can be controlled in a cooperative older child, fogging the lens of the sound eye provides a more cosmetically acceptable form of occlusion treatment. The lens can be fogged by applying a commercially available Bangerter foil to the lens or by simply using a brand of tape that is translucent but not transparent (Fig. 11.11.10). Clear films commonly used to line kitchen shelves or drawers can be used to achieve effective lens fogging. Fogging a lens works especially well along with atropine drops placed in the sound eye in children with hyperopia. The blur caused by uncorrected hyperopia combined with atropine will discourage the child from looking over the glasses.

## Atropine Penalization

Atropine drops placed in the sound eye may encourage use of the amblyopic eye for near tasks. Atropine 1% is commonly prescribed for use once daily. An advantage of this method of treatment is that it requires no compliance on the part of the child, other than wearing any needed glasses. In uncooperative children, the drops can be instilled while they are asleep. Some children will show an improvement in acuity with drops applied just 2 days per week.<sup>39</sup> If no improvement in vision is detected, the frequency

**Fig. 11.11.9 Pirate-Style Patch.** Children can easily peek by using a face turn to look around the patch or can easily remove the patch.

**Fig. 11.11.10 Taped Lens.** Translucent tape applied to lens of sound eye is more cosmetically acceptable than adhesive patches.

of drop instillation should be increased. Parents should be informed that with daily atropine use, the drop should be instilled each day even when the pupil remains dilated because a dilated pupil is not a reliable indicator that accommodation is paralyzed. When atropine penalization fails to produce improvement in acuity, patching or fogging should be added to the treatment regime. Parents need to be educated about the potential pharmacological side effects of atropine and ensure that it is not accessible to young children who may ingest it accidentally.

## Optical Penalization

Modifying the eyeglass prescription in a way that encourages fixation with one eye for near and the other for distance also can be used as a treatment for amblyopia.<sup>40</sup> For example, the sound eye may be corrected for near fixation and the amblyopic eye for distance. This form of treatment is not commonly applied; it can, however, be effective, particularly when the amblyopia is mild.

## Systemic Pharmacological Treatment

Occlusive and penalization treatments for amblyopia can only be effective during the critical period of visual system development. The aim of systemic pharmacological treatment is to facilitate treatment during the critical period and to extend the critical period in older children with amblyopia to enable them to respond to treatment. Studies using animal models have demonstrated that neurotransmitters can perhaps make this possible.<sup>41</sup> Among the neurotransmitters studied are the anticholinesterase inhibitor donepezil, the serotonin receptor inhibitor fluoxetine, the catecholamine modulator citicoline, and the dopamine precursors carbidopa and levodopa. Some of these agents have been studied in humans. Levodopa and carbidopa, in particular, have gained much attention. Studies have shown that low doses of levodopa, alone or together with carbidopa, have been shown to augment the effect of occlusion therapy,

even in children over age 12 years.<sup>42</sup> Systemic pharmacological treatment for amblyopia, however, has not yet achieved mainstream acceptance in clinical practice, and its efficacy has been challenged by studies that have shown that no difference exists in treatment outcome between a placebo and levodopa with carbidopa.<sup>43,44</sup>

## COURSE AND OUTCOME

A key variable to the course and outcome of amblyopia treatment is the plasticity of the visual system. This plasticity can and does both help and hinder amblyopia treatment. Successful amblyopia therapy can only occur when the visual system is plastic. If treatment is too aggressive without an adequate follow-up schedule, however, this plasticity can enable the sound eye to become amblyopic (reverse amblyopia) as well. Caution must be used to avoid causing amblyopia in the previously sound eye. Very young children are especially at risk for this because their visual system is more plastic. Plasticity of the visual system can enable amblyopia to recur when treatment is discontinued. Approximately one-fourth of successfully treated amblyopic children experience a recurrence within 6 months of treatment cessation.<sup>45</sup> Therefore, even when the maximal benefit of amblyopia treatment has been reached after the most aggressive tolerated treatment, the treatment should not be discontinued abruptly. Rather, the treatment should be adjusted to maintain the achieved acuity. This can be accomplished either with a gradual reduction in the number of hours of occlusion or with a gradual reduction in the number of days per week of atropine drop instillation.

Strabismus surgery is traditionally deferred until after amblyopia has been treated successfully. The assumption is that surgical results are improved as a result. A retrospective study suggested that surgical results are not dependent on preoperative treatment of amblyopia.<sup>46</sup> Treatment of amblyopia before surgery, however, may result in better parental compliance with regard to surgery, and evaluation of visual acuity by fixation preference is easier if the eyes are strabismic. In addition, if amblyopia is successfully treated before surgery, postoperative occlusion for maintenance of acuity will be minimal and thus is less likely to disrupt peripheral fusion.

## CONSIDERATIONS

For some patients, the creation of a better-sighted “spare tire” (in case of trauma or disease claiming the sound eye) is logically all that can be promised. An interesting study showed a threefold greater risk of loss of the sound eye when the other is amblyopic.<sup>47</sup> With the consideration that vision can be improved from a level of legal blindness to 20/20 if amblyopia is detected and treated early enough, the importance of early detection and treatment becomes very clear. It is not uncommon for older patients who develop ocular disease late in life to undergo multiple surgical procedures, injections, or oral and topical medical treatments to restore or preserve vision. Yet, in a young child with amblyopia, a simple, inexpensive eye patch can permanently restore vision as long as the eye remains healthy through the child’s entire lifetime.

# Forms of Nonsurgical Strabismus Management

Kyle E. Miller, David B. Granet, Gary R. Diamond<sup>†</sup>

# 11.12

## Definitions:

- **Orthoptics:** a wide range of techniques used to expand fusional vergence amplitudes and permit improved single binocular vision.
- **Convergence insufficiency:** a deficiency in convergence of the eyes to focus on a near target causing symptoms, such as difficulty reading.

## Key Feature

- Numerous techniques other than glasses are available to treat strabismus and should be considered before strabismus surgery is performed.

## ORTHOPTICS

The treatment of strabismus by means of orthoptics (literally “straight eyes”) has a long history, although perhaps this technique is used more extensively in Europe than in the United States. Its basic principle is the gradual expansion of fusional vergence amplitudes with exercises, either in open space or using targets viewed through devices intended to isolate the eyes—haploscopic devices—such as the major amblyoscope. Fusional vergence amplitudes also can be expanded through the use of gradually stronger prisms held in the appropriate direction before one or both eyes or through the use of spherical lenses to utilize the accommodation–convergence relationship to change ocular alignment. More recently, use of dichoptic images of increasing separation has been demonstrated to increase fusional amplitudes.

Historically, the success of orthoptic training was greatest in cooperative patients who had phorias (especially exophoria) or intermittent strabismus of comitant nature. The patients who suffered alphabet-pattern strabismus, torsional symptoms, or highly incomitant strabismus and who gave little cooperation fared less well. Patients affected by long-standing constant tropias were less likely to regain fusional vergence amplitudes despite orthoptic training. There are few published series of successfully treated patients followed up for long terms. It is unclear whether orthoptic training must be continued throughout life to be effective. It also is unclear whether preoperative fusional expansion might improve long-term surgical results.

Today, the most common indication for orthoptic training is convergence insufficiency (CI). The Convergence Insufficiency Treatment Trial randomized 221 children to four different treatment groups: (1) office-based vergence/accommodative therapy with home reinforcement (OBVAT), (2) home-based pencil push-ups (HBPP), (3) home-based computer vergence/accommodative therapy and pencil push-ups (HBCVAT+), or (4) office-based placebo therapy with home reinforcement (OBPT). Although flawed, with no randomization for children with attention deficit disorder/hyperactivity disorder (ADD/HD) and using a symptom survey tool, it remains a valuable source for qualitative information regarding treatment of CI. They found that after 12 weeks of therapy, 73% of those in the OBVAT had successful outcomes. Nearly half of those in the HBPP group and a third of those in the HBCVAT+ group also met the success criteria.<sup>1</sup> A follow-up study showed that the effects of treatment were sustained for at least 1 year in all groups.<sup>2</sup> Despite the increased success rate for office-based orthoptic therapy, the increased time and cost burden of

this therapy has left many to start with home-based therapy as a first-line treatment for CI.

Diplopia recognition (antisuppression) training for patients who have anomalous retinal correspondence and suppression is performed rarely today because of the risk of intractable diplopia.

## PRISMS

Prisms often are very useful in the treatment of certain patients who have a small degree of horizontal and vertical strabismus (especially when comitant).<sup>3,4</sup>

Patients who have superior oblique muscle palsy and a vertical deviation in the primary position may benefit from a vertical prism before the paretic eye. The usefulness of this technique is confounded by the simultaneous excyclotorsion associated with this palsy; some patients, however, cyclofuse successfully if the vertical deviation is collapsed with a prism. The minimal amount of prismatic correction necessary to provide comfortable single binocular vision is prescribed after an office and home trial with Fresnel membrane prisms, as described later in the chapter. Because many patients who suffer from this palsy have incomitant deviations when viewing from right to left, the field of single binocular vision is likely to be limited. In addition, vertical fusional vergence amplitudes are likely to wither under prism correction, and the patient becomes more strabismic when the prism is removed.

Some patients who have sixth nerve palsies and esotropia in primary position benefit from a base-out prism over the paretic eye; this may obviate the need for a face turn to view in the forward position. Some patients who have congenital nystagmus and a compensating face posture may benefit from prisms before one or both eyes to position the null point of least nystagmus and best acuity in the forward position with the head straight. In the case of a horizontal face position, the bases of the prisms are placed in the direction of the face turn. Because the amount of prismatic correction is quite large, this approach usually is impractical.

The use of prisms to treat patients who have typical intermittent horizontal and vertical strabismus often is contraindicated because they place fusional vergence amplitudes at rest and consign the patient to permanent, often increasing, prismatic correction. Certain older or debilitated patients may, however, benefit from prismatic correction when surgery is not indicated or when the deviation is small and symptomatic.

The prism adaptation test involves the preoperative use of prisms to neutralize a deviation with prisms for a given period, followed by surgery for the amount of strabismus fully neutralized by the prisms. Thus, the prism neutralization may be used to predict the outcome of surgery for a given deviation, to determine the maximum deviation, and to estimate fusion potential at that deviation (Fig. 11.12.1). In addition, some patients exhibit a different deviation with the prism adaptation test from that with cover testing. In a controlled, randomized study of patients who had acquired esotropia, 60% underwent prism adaptation, and 40% did not; of those who responded to prisms with motor stability and sensory fusion, half underwent conventional surgery, and half underwent augmented surgery based on the prism-adapted deviation.<sup>5</sup> Success rates were highest (89%) in the prism adaptation responders who underwent augmented surgery, 79% in those who underwent traditional amounts of surgery, and lowest (72%) in those who did not undergo prism adaptation.

The amount of prism to give a patient for comfortable single binocular vision may be assumed arbitrarily to be one-third to one-half of the maximal phoria obtained on cover testing, or it may be titrated to the subjective response of the patient.<sup>6</sup> The amount also can be tested using free

<sup>†</sup>Deceased

**Fig. 11.12.1 Prism Adaptation Test.** A child with esotropia is wearing a Fresnel membrane prism over the left eye, of sufficient strength to neutralize the esotropia.

**Fig. 11.12.2 A Fresnel Membrane Prism.** The prisms are prepunched in circular format, and the base is clearly marked.

prisms in space or using the prism attachment on a phoropter. Fresnel membrane prisms are obtained easily, are relatively inexpensive, and are easy to adjust in strength (Fig. 11.12.2). They are somewhat dysaesthetic, yellow, peel after about 3 months in place, and do degrade acuity (about one line per  $5\Delta$ ). Available in the range  $1\Delta$ – $30\Delta$ , they may be confined to one or both lenses (plano carriers in the case of patients who are not wearing a correction); trimmed to fit a bifocal segment, distance correction, or part of the field of a lens or may be prescribed to an oblique axis orientation for those who have both horizontal and vertical deviations. Patients are given a trial of Fresnel prism wear, and if it is agreeable with a relatively small deviation (under about  $10\Delta$ ), the prism may be ground permanently into spectacles. Some patients prefer to continue to wear the Fresnel membrane prism and simply change it, as needed.

## BOTULINUM TOXIN

The use of type A *Clostridium botulinum* toxin (Fig. 11.12.3) to temporarily paralyze human extraocular muscles by chemodenervation and thus permit the antagonist to contract and effect a permanent alignment change is credited to Scott et al.<sup>7</sup> at the Smith-Kettlewell Eye Research Foundation. The toxin interferes with acetylcholine release from nerve endings by antagonization of serotonin-mediated calcium ion release. The toxin usually is injected in the conscious patient, with the syringe needle connected to an auditory electromyography (EMG) device that amplifies the muscle action potentials (Fig. 11.12.4). Some practitioners inject through conjunctiva without EMG; however, there is no auditory or visual confirmation of placement, and this may lead to a higher rate of reinjections. Alternatively, the muscle may be injected under direct visualization under a local or general anesthetic. Within 3 days, the injected muscle becomes paralyzed, and an overcorrection is initially noted.

Many series of patients have been reported. In a series reported by Biglan et al.,<sup>8</sup> best results were found in patients who had surgical overcorrections (87.5% controlled with oculinum) and mild sixth nerve palsy (43.7% controlled) and worst results in patients who had comitant exotropia (13.3% controlled) and infantile esotropia (33.3% controlled). Significant

**Fig. 11.12.3. Vial of Reconstituted Type A *Clostridium botulinum* Toxin.** The toxin comes in a freeze-dried state and must be gently reconstituted prior to injection. (Image courtesy Erika C. Acera, O.C.[C].)

**Fig 11.12.4.** Electromyography (EMG) device for injecting intramuscular botulinum toxin in an awake patient. The syringe is attached to the dark green needle hub in this picture. As the needle is advanced into the muscle the tone made by the machine changes allowing the user to know when to inject. (Image courtesy Erika C. Acera, O.C.[C].)

complications included blepharoptosis, hypertropia, globe perforation, and subconjunctival hemorrhage. Complications reported by others include transient pupillary dilation, retrobulbar hemorrhage, spread of paralysis to noninjected muscles, missed injection site, patient disorientation, diplopia, and corneal irritation.<sup>9</sup>

Botulinum treatment appears to be most useful in patients who are not medically fit for surgery (because of illness or a history of malignant hyperthermia), who refuse surgery, who have had multiple strabismus operations, or who have acute sixth nerve palsies and mild esotropia in primary position. Botulinum use is contraindicated in patients who have a history of myasthenia gravis and is less effective in patients who have restriction of eye movement caused by scar tissue or entrapment of tissue, but it does have a role in the treatment of thyroid-related ophthalmopathy.<sup>10</sup>

## BUPIVICAINE

The use of bupivacaine (Fig. 11.12.5) has been more recently reported as a potential treatment for strabismus by Scott et al.<sup>11</sup> As opposed to the muscle relaxation created by the use of botulinum toxin, bupivacaine works on the injected muscle by causing it to remodel and shorten via hypertrophy. The method of injection is the same as in botulinum toxin. In a series of 55 consecutive patients with comitant horizontal strabismus, stable outcomes were observed for up to 5 years after injection.<sup>12</sup> As with botulinum toxin, the patients who would likely benefit the most from this treatment are those unable to tolerate general anesthesia or have other contraindications to incisional surgery.

**Fig 11.12.5.** Vial of bupivacaine. No reconstitution is necessary. (Image courtesy Kyle E. Miller, MD.)

## OCCLUSION

Although unsatisfactory to the patient and physician, occluding (or blurring) an eye for intractable diplopia related to strabismus remains an option. Sometimes this can be achieved with the use of an adhesive patch, cloth patch, blurring lens in glasses, Bangertner filter on spectacles, a blurring contact lens, or a black-centered contact lens.

# Techniques of Strabismus Surgery

Shira L. Robbins

# 11.13

**Definition:** Strabismus surgery is physical manipulation of the extraocular muscles with the goal of therapeutic benefit.

## Key Feature

- The ideal strabismus surgery needs to merge fusional potential garnered through preoperative testing with education about realistic patient expectations and excellent surgical technique.

## INTRODUCTION

Strabismus can lead to frank diplopia, visual shadowing, visual confusion, asthenopia, headaches, dizziness, anomalous head position, decreased visual field, impaired stereopsis, and a large impact on an individual's social and economic positions. Because of the myriad symptoms and functional limitations, treatments are commonly warranted. Strabismus surgery is an important part of the treatment armamentarium in addressing strabismus. In most patients, nonsurgical techniques have been employed with suboptimal results prior to surgical intervention. Many of these nonsurgical methods are discussed in Chapters 11.6–11.11. It is important that prior to surgery, reproducible measurements are obtained, that the patient is sufficiently systemically stable to be able to tolerate the procedure and the accompanying anesthetic/analgesia, and that the patient (or parent) understands the goals and limitations of the planned surgery. In addition, careful preoperative testing to evaluate for postoperative diplopia is imperative to ensure patient satisfaction.

Except in unusual cases, the following are goals of all strabismus surgery:

- Attaining peripheral fusion with fusional vergence amplitudes sufficient to maintain alignment of the eyes.
- Achieving comfortable single binocular vision (horizontal, vertical and torsional) to enable the patient to perform visual tasks without asthenopia.
- Minimizing anomalous head positions to maintain single binocular vision.
- Restoring appearance as close to normal as possible.

## HISTORICAL REVIEW

The first eye muscle procedure (horizontal rectus muscle tenotomy) was probably performed in the middle of the eighteenth century by Chevalier John Taylor.<sup>1</sup> The first successful operation for strabismus with the use of horizontal rectus tenotomy was performed on a living patient (a 7-year-old boy with esotropia) in 1839 by Johann Dieffenbach.<sup>2</sup> Von Graefe<sup>3</sup> performed partial tenotomy in 1851 and advancement of a rectus muscle in 1857. By the late nineteenth century, sutures were being used to shorten a muscle, and measured resections and recessions followed soon afterward. More recent contributions include the use of adjustable sutures and techniques for operation on the oblique and vertical rectus muscles.

In modern times, advances have been made in magnification techniques, improved overhead and loupe mounted lighting, instrument technology, suture development, injectable strabismus treatments, and imaging. Contemporary sutures for strabismus surgery often are absorbable and swaged to needles. The needles are typically spatulated with cutting edges directed away from the center of the globe. The cutting edges are on the sides of a spatulated needle making cutting through a tissue plane easier while not cutting above or below the needle, thus decreasing the risk of scleral perforation.

## BOX 11.13.1 Strabismus Surgery: Preoperative Evaluation and Testing

Sensory testing is performed in all patients whenever permitted by age and ability to cooperate.

Testing should, at minimum, include tests for type of fusional ability and quantity of stereoscopic appreciation.

Measurement of visual axis deviation. Prism adaptation therapy may be helpful in quantifying a target angle of strabismus.

In cooperative children and adults: cover tests, including tests for detection and quantitation of phorias and tropias, tests for binocular single vision and corrected deviation induced diplopia.

In very young children: the Krimsky or cover/uncover tests to quantitate tropias.

Exhaustion of nonsurgical treatment methods including, when appropriate, glasses, patching, fusional amplitude enhancement and prisms.

## PREOPERATIVE EVALUATION AND DIAGNOSTIC APPROACH

Ideal preoperative evaluation of the strabismus surgical patient includes quantification of the misalignment in primary positions at distance and at near, in the nine diagnostic gaze positions, and in right and left head tilt (Box 11.13.1). In most patients, the maximal deviation under conditions of complete dissociation of the visual axes is the deviation for which surgery is to be designed. This is altered in cases of anomalous sensory adaptation (see Chapter 11.4). Patients with diplopia are assessed with prisms in free space to determine the amount of horizontal and/or vertical correction needed to fuse in both the primary position and at near. Patients with sensory adaptations, such as suppression, are evaluated to determine if they have the potential to fuse and are tested for postoperative diplopia. Finally, duction and version testing and, when appropriate, forced duction and force generation testing are performed. These topics are discussed in greater detail in Chapter 11.3.

## ANESTHESIA

The choice of anesthetic technique is individualized and depends on the circumstances of the procedure chosen, age, comorbidities, ability of the patient to tolerate discomfort, and patient's choice. Strabismus surgery on children younger than age 16 years usually requires general anesthesia. Many adult patients are uncomfortable with the operating room setting and/or the concept of eye muscle surgery and request general anesthesia. The benefit of general anesthesia is an immobile, insensate patient. The disadvantages include the attendant risks of general anesthesia and increased recovery time. In cases where local anesthesia is used, conversion to general anesthesia may be necessary occasionally.

When planning a retrobulbar injection, preinjection of intravenous dissociative agents or narcotics is often helpful, and lid block is usually not required. Retrobulbar injection may provide sufficient akinesia and anesthesia for cooperative older teenagers and adults to enable them to tolerate strabismus surgery. The benefits of retrobulbar injection include obviation of general anesthesia risks, briefer recovery room time, and more rapid return to normal routine. The disadvantages include risks of globe or nerve perforation,<sup>4</sup> rare cases of presumed brainstem anesthesia with respiratory suppression,<sup>5</sup> inability to immobilize the superior oblique muscle, inability to operate on both eyes in one session unless another technique is used for the second eye, and injection into a muscle belly with resultant damage.

Particular caution must be exercised in those who have large globes or encumbered orbits (patients who have dysthyroid orbitopathy and enlarged extraocular muscles) because of the increased risk of globe perforation, intramuscular injection, or vascular compromise.

Many cooperative older patients can tolerate epibulbar injection of anesthetic agent around the appropriate muscle(s). Generally, the patient who tolerates forced duction testing in the office is a candidate for epibulbar injection or even topical anesthesia. The advantages of epibulbar injection are similar to those of retrobulbar injection; the disadvantages include somewhat greater discomfort (especially when the muscle is hooked) and rare cases of globe perforation. Reoperations dissecting through scar tissue may not be tolerated with local anesthesia modalities. The advent of the delayed adjustable suture technique allowing adjustment much later in the postoperative period eliminates the need to choose the type of anesthesia according to the desired time to perform an adjustment.

Newer anesthetic agents may decrease postoperative nausea and vomiting. Anesthesiologists need to be prepared to medically support bradycardia secondary to the oculocardiac reflex.

## GENERAL TECHNIQUES

Strabismus surgery demands meticulous planning. Surgical findings of muscle configuration and forced ductions often alter the decision-making process. It is helpful to keep a description of the prior eye/strabismus surgeries, sensorimotor examination and proposed surgical plan for ready reference before and during surgery.<sup>6</sup>

The main types of strabismus surgeries are outlined in [Box 11.13.2](#). The exact location and number of conjunctival incisions depend on the muscles to be operated, pre-existing scarring, and the patient's previous surgical history. Limbal incisions more easily permit accurate surgery without the presence of a trained assistant, may expedite surgery in patients who have experienced multiple procedures on a given muscle, may minimize conjunctival shredding in older patients who have limited Tenon's capsule and inelastic conjunctiva, and permit conjunctival recessions if the tissue is contracted.<sup>7</sup> Patients, however, experience increased discomfort because of corneal proximity; the incisions may compromise the conjunctival contribution to the anterior segment circulation; and the incisions heal more slowly than when other options are used.

Forniceal incisions permit rapid access to the muscles, stimulate less discomfort than limbal incisions, preserve conjunctival vascular supply, and may not require suture or diathermic closure.<sup>8</sup> However, they do require the presence of a more skilled assistant, a better knowledge of muscle anatomy to avoid surgery on the wrong muscle, and relatively elastic conjunctiva. It is important not to incise conjunctiva more than 8 mm posterior to the limbus to avoid the risk of invading orbital fat.

Incisions at the anterior border of the muscle tendon (Swan's approach)<sup>9</sup> have fallen from favor because of the tendency for significant postoperative subconjunctival scarring between the limbus and the muscle insertion.

Absorbable sutures generally are utilized when vascular healing of tissues occurs, as in typical recession and resection techniques. Small-caliber 8-0 conjunctival sutures generally absorb within 7–10 days if covered with conjunctiva, slightly longer if exposed. As opposed to the 6-0 Polyglactin 910 (Vicryl, Ethicon) muscle sutures that typically absorb within 56–70 days. Some advocate permanent sutures if avascular tissue, such

as the superior oblique tendon, is harnessed, as in the superior oblique muscle tuck or silicone (Silastic) band-lengthening procedure. Many also use permanent sutures on the inferior rectus muscle to avoid late overcorrections and elongated scarring.

## SPECIFIC TECHNIQUES

### Recession of a Rectus Muscle

#### Lateral Rectus

There are many variations of strabismus surgery technique and instrumentation. The following is a description of common techniques employed by the author at the University of California San Diego. Forced duction (FD) testing should be considered to obtain information on the tension of the muscles and other causes of restriction in all surgical cases, especially with incomitance and limited clinical ductions. FDs are accomplished by grasping the conjunctiva at the limbus 180° apart and proptosing the globe while pushing away from the muscle in question, thus allowing the recti to be on stretch ([Fig. 11.13.1](#)). This can be repeated for all four recti. Thorpes forceps reduce conjunctival trauma with a 3:2 tooth configuration. The globe is then retropulsed and tortored to put the oblique muscles on stretch to demonstrate restriction or laxity ([Fig. 11.13.2](#)). Exaggerated FD testing can be very helpful in cases of superior oblique muscle pathology.<sup>10</sup>

To perform a lateral rectus muscle recession, the assistant grasps the eye at the conjunctiva–Tenon's capsule junction with a 0.3-mm locking forceps and rotates the eye into elevation and adduction. When an assistant is not present, a traction suture can be placed. The surgeon then elevates the conjunctiva at the base of the fornix and incises the conjunctiva approximately 8 mm from the limbus ([Fig. 11.13.3](#)). The Tenon's capsule is grasped within the conjunctival incision, applying gentle pressure away from the sclera and elevating it from the globe. Tenon's capsule is then incised to expose bare sclera. Visualization of the bare sclera is maintained by leaving the posterior forceps in place.

A Stevens hook is passed to isolate the inferior lateral rectus fibers by keeping the hook tip on sclera ([Fig. 11.13.4](#)). Topical analgesia mixed with epinephrine can be used at any time during the procedure for perioperative analgesia and hemostasis. A Greene self-retaining muscle hook is then passed behind the Stevens hook with the flat edge of the tip on sclera, isolating the full lateral rectus muscle. It is important that no posterior movement of the hook is used so that the inferior oblique fibers are not mistaken for part of the lateral rectus ([Fig. 11.13.5](#)). A second Greene hook is placed posterior to the original Greene hook with a slight turn toward

**Fig. 11.13.1 Forced Duction Testing of Horizontal Rectus Muscles.** The limbal conjunctiva is grasped and the globe is proptosed to place the recti on stretch. Movements of restriction or laxity can then be identified. (All photography in this chapter by Peter Durdaller.)

### BOX 11.13.2 Strabismus Surgery Techniques

#### Weakening Procedures

Recession:	Moving posteriorly
Lengthening:	Myotomy—cutting part of muscle
Tenotomy:	Cutting part of tendon
Spacer:	Suturing inert foreign body
Myectomy:	Excising part or completely detaching from eye
Posterior Faden:	Decreasing mechanical advantage in field of action
Extirpation/Denervation:	Removing nerve stimulation
Chemically induced:	Using botulinum toxin

#### Strengthening Procedures

Shortening:	Resection—removing piece without changing insertion location
	Tuck/Plication—creating fold in muscle via suture
	Advancement—moving anteriorly
Chemically Induced:	Using lidocaine
Redirecting Force of Action:	Transposition—moving insertion to new axis

**Fig. 11.13.2 Forced Duction Testing of the Oblique Muscles.** The limbal conjunctiva is grasped and the globe is retro-pulsed to place the oblique muscles on stretch. Movements of restriction or laxity can then be identified.

**Fig. 11.13.4** The Stevens hook is used to isolate the inferior fibers of the muscle by maintaining the tip on sclera. This creates a clear path for a larger hook.

**Fig. 11.13.3 Recession of Lateral Rectus Muscle.** Figs. 11.13.3 through 11.13.19 demonstrate recession of the left lateral rectus muscle. A locking forceps is placed at the 5 o'clock position and used to elevate and adduct the eye. A Thorpe's forceps is used to elevate the conjunctiva about 8 mm posterior to the limbus augmenting the conjunctival incision.

**Fig. 11.13.5** A Greene or Jameson muscle hook is inserted posterior to the Stevens hook under the tendon of the lateral rectus muscle. The toe of the hook is kept flat against the sclera at all times.

the limbus after there is a tactile sense of isolating all muscle fibers. This ensures the distal fibers will remain on the hook while degloving the conjunctiva and the Tenon's capsule with a Stevens hook. Some surgeons prefer to use a Jameson hook. Once the muscle is degloved (Fig. 11.13.6), scissors are used to incise the superior aspect of Tenon's fascia (Fig. 11.13.7). Through this opening, a Stevens hook is placed, with the tip on the sclera. A pole test ensuring that no splitting of the muscle fibers is accomplished by leaving the Stevens tip on the sclera while arcing toward the limbus

(Fig. 11.13.8). If there are split fibers, the hook tip will meet with resistance. Using direct visualization with the assistance of a variety of hooks is advised if there is any resistance. The presence of heme at this step is often a sign of split muscle, requiring further investigation. With the use of two Stevens hooks, the anterior connective tissue is placed on stretch and cut with scissors (Fig. 11.13.9). The connective tissue adhered to the muscle tendon at the insertion can be further cleared with an Afrin-soaked cotton tip applicator using a posterior motion. Two Stevens or Von Graefe hooks are passed posteriorly along the tendon edges, against bare sclera,

**Fig. 11.13.6** The small Stevens hook is moved forward and backward over the tendon and under the conjunctiva. This separates conjunctiva from the underlying Tenon's capsule and tendon degloving it.

**Fig. 11.13.8** A Stevens muscle hook is placed perpendicular to the sclera through the incision. It is swept around the superior pole of the tendon to ensure that the entire tendon is captured on the muscle hook, the pole test.

**Fig. 11.13.7** A scissors is used to incise the Tenon's fascia at the superior pole of the tendon.

**Fig. 11.13.9** Two Stevens hooks are used to stretch the anterior connective tissue from the insertion in preparation for dissection with scissors.

and elevated to expose the intermuscular fascia for dissection close to the muscle belly. The common fascial attachments between the lateral rectus and inferior oblique muscles are removed to avoid undesired effects on oblique muscle functions.

The muscle is sewn 1 mm posterior to the insertion with a 6-0 suture. The author's preference is a double-armed, Polyglactin 910 (Vicryl, Ethicon) on S-29 needle. The needle is passed partial thickness from the middle to the inferior edge of the tendon (Fig. 11.13.10). A full-thickness, locking whipstitch is placed at the edge of the tendon (Fig. 11.13.11). The same technique is used with the opposite suture end to the superior muscle

pole (Fig. 11.13.12). A tight muscle can be sewn with the use of a beveled hook, which protects the sclera during this step. The muscle is disinserted using Manson-Aebli scissors in several cuts with the anterior blade being slightly elevated (Fig. 11.13.13). After the first snip, a 0.5-mm Castroviejo locking forceps are placed on the first muscle pole stump disinserted to allow control of the globe, followed by the second forceps at the remaining muscle stump.

The caliper is positioned at the end of the original insertion (Fig. 11.13.14) to the target recession distance posteriorly. This creates an indentation used as a base for the scleral pass, where the needle is laid flat with

**Fig. 11.13.10** The muscle is sewn partial thickness from the center to the inferior pole.

**Fig. 11.13.11** A full-thickness whipstitch is placed at the tendon edge.

the tip engaging the edge of the scleral depression (**Fig. 11.13.15**). In most cases, it is important to maintain a wide insertion to avoid central sagging of the muscle. An ideal scleral pass can be conceptualized as a mole burrowing a tunnel, whereby the overlying sclera will appear elevated. A common style of scleral pass is the crossed swords, popularized by Marshall Parks, which is thought to increase stability of the new muscle insertion (**Fig. 11.13.16**).<sup>11</sup>

The sutures are then pulled in the direction in which they were passed to avoid ripping the sutures out of the sclera and then tied (**Fig. 11.13.17**). Care must be taken to pull both needles out of the sclera prior to pulling the majority of the suture through; thus, decreasing the likelihood of shredding suture from the opposite needle. Some surgeons close the Tenon's

#### PARTIAL THICKNESS DOUBLE ARMED SUTURING WITH LOCKING SIDE BITES

**Fig. 11.13.12** Partial-thickness double-armed suturing with locking side bites is performed.

**Fig. 11.13.13** The tendon is disinserted from the globe.

capsule separately, although most do not. The overlying conjunctiva is closed with buried 8.0 Polyglactin 910 (Vicryl, Ethicon) or other suture of choice (**Figs. 11.13.18 and 11.13.19**). Sub-Tenon's analgesia is applied.

#### Medial Rectus and Vertical Recti

The principles of recession are the same as described previously for the lateral rectus muscle. Recession of the vertical recti, however, includes visualization and preservation of the neighboring oblique muscles before the procedure is performed. The frenulum between the superior rectus and superior oblique muscles is visualized and incised. The lower eyelid retractor muscles must be carefully dissected from the inferior rectus muscle to avoid lower lid ptosis. This is best performed close to the rectus muscle to avoid fat pad violation.

#### Resection of a Rectus Muscle

##### Lateral Rectus

The muscle is isolated, cleaned, and dissected posteriorly, employing the same technique as the above recession. A second Greene muscle hook is passed beneath the tendon, and traction is applied between the two muscle hooks which are kept parallel to the insertion. A caliper is used

**Fig. 11.13.14** The appropriate position for muscle reattachment is measured from the original insertion.

**Fig. 11.13.16** The second needle of the double-armed suture is placed in similar fashion to the first with overlap of the exit sites creating the "crossed swords" technique.

**Fig 11.13.15** The indentation left by the caliper is used as a base of the needle approach through partial thickness sclera.

**Fig. 11.13.17** The muscle sutures are pulled through sclera in the direction they were placed and secured.

to measure the amount of desired resection. Observing anatomic landmarks (i.e., vascular details) can assist with "seeing" the target point. A central full-thickness bite is taken with a 6.0 double armed Polyglactin 910 (Vicryl, Ethicon) suture on S-29 needle and tied in a square knot ([Fig. 11.13.20](#)). The arms are then passed partial thickness to the edge of the muscle with two locking whipstitch bites at the muscle poles ([Figs. 11.13.21](#) and [11.13.22](#)).

A straight Jakes hemostat is placed across the tendon just anterior to the suture line. The tendon is disinserted in the same manner as the recession ([Fig. 11.13.23](#)). The muscle stump from the cut edge to the hemostat

is excised with scissors ([Fig. 11.13.24](#)). Cautery is applied to the fibers at the hemostat followed by balanced salt solution (BSS) prior to removing the hemostat.

The 6.0 S-29 needles are then passed at the original insertion from the posterior to the anterior side ([Fig. 11.13.25](#)). It is necessary to remember that the scleral thickness is at its minimum just posterior to the insertion. At no time should the needle be pointed toward the globe. Calipers can be used instead to compress the scleral layers and serve as a base for the needle to approach the tissue almost parallel. An alternate technique is to pass the needle through the tendon scleral shelf junction, as shown in [Fig.](#)

**Figs. 11.13.18, 11.13.19** The incision is reapproximated with interrupted buried suture.

**Fig. 11.13.20** Resection of a Rectus Muscle. **Figs. 11.13.20 through 11.13.30** demonstrate a resection of the left lateral rectus muscle. The same steps as described in "Recession surgery" are used to isolate the rectus muscle. The muscle is put on stretch, and a caliper-measured central full-thickness bite is secured by using a double-armed suture.

**Fig. 11.13.21** A partial-thickness pass from the center to edge is placed.

**11.13.26.** Crossed swords can be used, and this facilitates maintenance of the tendon width and close proximity for tying (**Fig. 11.13.27**).

The resected muscle often has some posterior tension. The globe is mildly abducted, and pressure can be placed on the external portion of the resected muscle by the assistant's hook to minimize the suture tension required to complete the knot. The muscle should be inspected to ensure no hangback has occurred (**Fig. 11.13.28**). The overlying conjunctiva is closed with 8.0 Polyglactin 910 (Vicryl, Ethicon) in a buried fashion (**Figs. 11.13.29 and 11.13.30**). Some use a remaining piece of the 6-0 muscle suture, although this can create more postoperative discomfort. Sub-Tenon's analgesia is applied.

### **Medial Rectus and Vertical Recti**

The principles of resection are the same as described previously for the lateral rectus. Resections of the vertical recti include visualization and

preservation of the neighboring oblique muscles before the procedure is performed as described above.

### **Other Surgical Techniques**

Readers interested in surgical approaches to the plication, superior oblique tendon and inferior oblique muscle, adjustable suture technique, and posterior fixation suture are referred to the following references: Wright and Strube,<sup>12</sup> Chaudhuri and Demer,<sup>13</sup> Lingua,<sup>14</sup> Parks,<sup>15</sup> Romano and Roholt,<sup>16</sup> Fierson et al.,<sup>17</sup> Robbins et al.,<sup>18</sup> and Guyton.<sup>19</sup>

**Fig. 11.13.22** Suturing of opposing partial-thickness passes with two side-locking bites is completed.

**Fig. 11.13.24** The resected tissue is excised from the clamp.

**Fig. 11.13.23** The tendon is disinserted.

**Fig. 11.13.25** The muscle is sewn through partial thickness sclera at the insertion.

## COMPLICATIONS

Significant strabismus surgery complications are uncommon ([Box 11.13.3](#)). Optimizing surgical technique assists in minimizing complications; underlying physiological tendencies, however, play a large role. Hemostasis is required at each step in the procedure, whichever conjunctival approach to the muscle is used. Attention to the corneal surface prevents inadvertent drying or instrument-derived abrasion. Particular caution is required with patients who have thin sclera (e.g., those with severe myopia), have a history of scleritis, or have undergone previous scleral procedures, especially when disinsertion is performed or the muscle is reattached to the

globe. The surgeon must be aware of the location of vortex veins during oblique muscle surgery.

## Violation of the Posterior Tenon's Capsule/Fat Adherence

Violation of the posterior Tenon's capsule permits release of orbital fat into the space contiguous to the globe, allowing fibrofatty proliferations that involve sclera and nearby extraocular muscles.<sup>20</sup> This usually occurs after surgery on the inferior oblique muscle but may occur after surgery on any

**Fig 11.13.26** Needle passage at a tangent to the globe. If this angle is used when the needle is returned through the insertional step of the sclera, the needle tip does not have to be directed toward the globe.

**Fig. 11.13.27** The needles can be placed in "crossed swords" fashion. This maintains normal tendon width.

muscle; the best prevention is to perform all incisions under direct visualization. If a Tenon's capsule perforation is recognized, an attempt can be made to repair the defect with absorbable sutures. In the case of inferior oblique muscle surgery, the patient often presents with a progressive hypotropia, esotropia, and exocycloptropia in the involved eye because of tightening of the tissues around the inferior rectus muscle. Surgical treatment in these cases is difficult and can be unpredictable.

### Anterior Segment Ischemia

Anterior segment ischemia with chemosis, corneal edema, uveitis, hypotony, iris sector paresis or cataract, a rare complication, appears to occur after strabismus surgery, mainly in older patients who have systemic vascular disease<sup>21</sup> or immunocompromising conditions. Surgeons

**Fig. 11.13.28** The resected muscle has been returned to the original insertion with no hangback.

#### BOX 11.13.3 Possible Complications of Strabismus Surgery

- Allergic reaction
- Anesthesia-related complications
- Anterior ischemic syndrome
- Conjunctival cyst, granuloma, and scarring
- Dellen
- Diplopia
- Eyelid retraction or ptosis
- Fat adherence
- Infection/Endophthalmitis
- Orbital inclusion cyst
- Over- or underresponse
- Refractive changes
- Scleral perforation
- Slipped, lost or ruptured muscle
- Stretch scar

traditionally avoid removal of more than three rectus muscles in one eye simultaneously or within 6 months of previous rectus muscle detachment. Hummelsheim or Jensen transpositions are favored over the Knapp transposition when ischemia is a consideration. Plications versus resections are thought to preserve more blood flow, and complex procedures, such as the California Hummelsheim procedure,<sup>22</sup> have been proposed for this reason. Anterior segment ischemia, however, has been described in rare cases when less surgery was performed, or the rectus muscles were not detached from the globe but rather were split and joined to others (Jensen procedure); it is thus difficult to provide exact guidelines. Most surgeons recommend caution in operations on patients who have systemic vascular disease or are immunocompromised, especially if vertical rectus muscle surgery is planned, because these muscles appear to contribute more significantly to anterior segment circulation. Preoperative iris angiography can be helpful in identifying patients potentially at risk. Evidence suggests that the avoidance of limbal conjunctival incisions preserves the conjunctivally transmitted oxygen contribution. Most patients who have postoperative anterior segment ischemia escape permanent visual sequelae if treated with frequent topical and/or systemic corticosteroids.

### Epithelial Cysts/Suture Granulomas

Epithelial inclusion cysts may form if the conjunctiva folds under itself at any incision site. Careful reapposition of the conjunctival incisions is

**Figs. 11.13.29, 11.13.30** Tenon's Capsule and Conjunctiva Are Replaced in Their Original Position. The incision is closed with interrupted buried sutures.

warranted. Occasionally, cysts or suture granuloma excision is required if anti-inflammatories and time do not suffice.

### Corneal Dellen

The contours of the postoperative conjunctiva lead to uneven tear distribution on the cornea. Corneal thinning occurs in the peripheral cornea adjacent to an area of conjunctival inflammation. Dellen occur more commonly in adults. If left untreated, corneal perforation is possible. With adequate treatment of frequent hydration they typically heal in days to weeks but are associated with temporary decreased visual acuity and pain.

### Globe Perforation

The most ominous adverse occurrence during strabismus surgery is globe perforation. If the needle passes in the suprachoroidal space, which is more likely in cases of thinned sclera (in those with high myopia, reoperations, etc.), it usually is seen as a small mound of brown material at the needle exit site. Treatment is controversial, with some suggesting use of barrier laser around the white linear area seen on dilated retinal examination and others advocating observation. If the retina is perforated, vitreous may appear at the needle entrance or exit site. This should be trimmed and the retina examined; any retinal detachment must be addressed promptly. Usually, the retina appears attached and the perforation site is surrounded by retinal hemorrhage. Appropriate immediate treatment in these cases also is controversial; some investigators recommend performing immediate laser photocoagulation or cryotherapy, others advocate observation only. Children have formed vitreous, and retinal detachment after perforation is rare. When retinal detachment occurs, however, the prognosis is guarded because of a typical delay in treatment.<sup>23</sup> If the depth of a scleral pass is questionable, the conservative approach of performing a dilated peripheral retinal examination is prudent. Rare cases of endophthalmitis associated with scleral perforations have been reported, making it important to consider the use of antibiotics in these cases.

### Underresponse or Overresponse

The most common "complication" after strabismus surgery is under- or overresponse. After a suitable period of observation—depending on the individual clinical situation—and a trial of nonsurgical treatment, reoperation may be necessary. When possible and appropriate, non-operated muscles can be approached, using the prior surgical response to inform surgical dosage planning.

### Lost or Slipped Muscles/Stretch Scar

Only the medial rectus muscle lacks a fascial connection to an oblique muscle, and thus it is the one most at risk of being "lost" should its sutural attachment to the globe slip. The medial rectus muscle retracts within the posterior Tenon's capsule against the medial orbital wall. Excellent illumination, exposure via an assistant or with traction sutures, and meticulous technique may enable the surgeon to reacquire the muscle. Particular care must be devoted to preservation of the Tenon's capsule and prevention of adherence syndrome. The striated muscle may "slip" within its capsule, which results in underaction but not paresis of the muscle<sup>24</sup>; careful examination of the site demonstrates capsule alone attached to sclera. The muscle itself is advanced to its intended position. Immediate reoperation is required as soon as the condition is suspected. If some time has elapsed, the rectus muscle contracts. The reattachment site is determined after consideration of the amount of strabismus and the amount of contracture. If the muscle cannot be identified, often a transposition procedure using the adjacent rectus muscle must be performed and the antagonist muscle crippled. Similarly, the muscle scar may stretch and therefore lose function. The stretch scar is excised and the tendon advanced to the intended position.<sup>25</sup>

### MUSCLE RUPTURE OR PULLED IN TWO SYNDROME (PITS)

Any extraocular muscle, but particularly the inferior and medial rectus muscles, can completely rupture during surgery. The largest reported series suggests this occurs at the tendon muscle junction and often in cases of prior trauma or thyroid induced strabismus.<sup>26</sup> The distal end often can be retrieved and primarily repaired with satisfactory results. Alternatively, a transposition can be considered, or, in the case of the inferior rectus muscle, the inferior oblique muscle can be harnessed to augment infraduction.

### OUTCOMES

Sensorimotor adaptation plays a large role in the stability of postoperative alignment. The effect of a muscle surgery can change over time. Surgical success rates are dependent on many variables, some of which are unique to a given clinical situation. Surgical results are described in the chapters on individual forms of strabismus.

# Clinical Anatomy of the Eyelids

Jonathan J. Dutton

## 12.1

**Definition:** The eyelids are mobile, flexible, multilamellar structures that cover the globe anteriorly.

### Key Features

- The eyelids provide protection from desiccation and airborne foreign matter.
- The eyelids anatomically contain both superficial musculo-cutaneous elements anteriorly and orbital components posteriorly.

## INTRODUCTION

The eyelids serve a vital function by protecting the globe. They provide fundamental elements of the precorneal tear film and help distribute tears evenly over the surface of the eye. The eyelids collect tears and propel them to the medial canthus, where they enter the lacrimal drainage system. The eyelashes sweep airborne particles from the front of the eye. Constant voluntary and reflex movements of the eyelids protect the cornea from injury and glare. Any aesthetic or reconstructive surgery on the eyelids requires a thorough knowledge of eyelid anatomy.<sup>1,2</sup>

## ANATOMY OF THE EYELIDS

The eyelids undergo a complex embryonic and fetal morphogenesis involving a succession of strictly regulated episodes of proliferation, fusion, and separation that results in functional eyelids at birth.<sup>3</sup> In young adults the interpalpebral fissure measures 10–11 mm vertically. With advancing age this decreases to only about 8–10 mm. The horizontal length of the fissure is 30–31 mm. The upper and lower eyelids meet at an angle of approximately 60° medially and laterally. In primary position, the upper eyelid margin lies at the superior corneal limbus in children and 1.5–2 mm below it in adults. The lower eyelid margin rests at the inferior corneal limbus.

The margin is covered by cutaneous epithelium and eyelashes anteriorly and conjunctiva with meibomian gland openings posteriorly.

### Orbicularis Muscle

The orbicularis oculi is a complex striated muscle sheet that lies just below the skin. It is divided anatomically into three contiguous parts (Fig. 12.1.1): orbital, preseptal, and pretarsal.<sup>4,5</sup>

The orbital portion overlies the bony orbital rims. It arises from insertions on the frontal process of the maxillary bone, the orbital process of the frontal bone, and the common medial canthal tendon. Its fibers pass around the orbital rim to form a continuous ellipse.

The palpebral portion of the orbicularis muscle overlies the mobile eyelid from the orbital rims to the eyelid margins. The muscle fibers sweep circumferentially around each eyelid as a half ellipse fixed medially and laterally at the canthal tendons. It is further divided topographically into the preseptal and pretarsal orbicularis.

The preseptal portion of the muscle is positioned over the orbital septum in both upper and lower eyelids. Its fibers originate perpendicularly along the upper and lower borders of the medial canthal tendon. Fibers arc around the eyelids and insert along the lateral horizontal raphe. The pretarsal portion of the muscle overlies the tarsal plates. Contraction of these fibers aids in the lacrimal pump mechanism.<sup>6</sup> Medially, the deep heads of the pretarsal fibers fuse to form a prominent bundle of fibers, Horner's muscle, that runs behind the posterior limb of the canthal

tendon. It inserts onto the posterior lacrimal crest. Horner's muscle helps maintain the posterior position of the canthal angle and may aid in the lacrimal pump mechanism.<sup>7</sup>

### Orbital Septum

The orbital septum is a thin, fibrous, multilayered membrane that begins anatomically at the arcus marginalis along the orbital rim. Distal fibers merge into the anterior surface of the levator aponeurosis (Fig. 12.1.2).<sup>8</sup> The point of insertion usually is about 3–5 mm above the tarsal plate, but it may be as much as 10–15 mm above it.<sup>9</sup> In the lower eyelid the septum fuses with the capsulopalpebral fascia several millimeters below the tarsus, and the common fascial sheet inserts onto the inferior tarsal edge.<sup>10,11</sup>

### Preaponeurotic Fat Pockets

The preaponeurotic fat pockets in the upper eyelid and the precapsulopalpebral fat pockets in the lower eyelid are anterior extensions of extraconal orbital fat. These are surgically important landmarks and help identify a plane immediately behind the orbital septum and anterior to the major eyelid retractors. In the upper eyelid, two fat pockets typically occur: a medial pocket and a central one.<sup>12</sup> In the lower eyelid, three pockets occur: medial, central, and lateral.<sup>13</sup>

### Major Eyelid Retractors

The retractors of the upper eyelid consist of the levator palpebrae and Müller's muscles.<sup>14,15</sup> The levator palpebrae superioris arises from the lesser sphenoid wing and runs forward just above the superior rectus muscle. Near the superior orbital rim, a condensation along the muscle sheath attaches medially and laterally to the orbital walls. This is the

**Fig. 12.1.1 Orbicularis and Frontalis Muscles.** (Adapted with permission from Dutton JJ. Atlas of clinical and surgical orbital anatomy. 2nd ed. London: Elsevier Saunders; 2011. p. 153.)

**Fig. 12.1.2 Orbital Septum.** (Adapted with permission from Dutton JJ. *Atlas of clinical and surgical orbital anatomy*. 2nd ed. London: Elsevier Saunders; 2011. p. 149.)

**Fig. 12.1.3 Levator Aponeurosis and Medial and Lateral Canthal Tendons.** (Adapted with permission from Dutton JJ. *Atlas of clinical and surgical orbital anatomy*. 2nd ed. London: Elsevier Saunders; 2011. p. 149.)

superior transverse orbital ligament of Whitnall. It provides some support for the fascial system that maintains spatial relationships between a variety of anatomical structures in the superior orbit.

From Whitnall's ligament the muscle passes into its aponeurosis (Fig. 12.1.3). This sheet continues downward 14–20 mm to its insertion near the marginal tarsal border. The aponeurotic fibers are most firmly attached at about 3–4 mm above the eyelid margin.<sup>15,16</sup> The aponeurosis also sends numerous delicate interconnecting slips forward and downward to insert onto the interfascicular septa of the pretarsal orbicularis muscle and subcutaneous tissue. These slips maintain the close approximation of the skin, muscle, aponeurosis, and tarsal lamellae and integrate the distal eyelid as a single functional unit. This relationship defines the upper eyelid crease in both white and black people.

As the levator aponeurosis passes into the eyelid from Whitnall's ligament, it broadens to form the medial and lateral “horns.” The lateral horn

forms a prominent fibrous sheet that indents the posterior aspect of the lacrimal gland and so defines its orbital and palpebral lobes. The medial horn is not as well developed. Together, the two horns serve to distribute the forces of the levator muscle along the aponeurosis and the tarsal plate.

In the lower eyelid, the capsulopalpebral fascia is a fibrous sheet that arises from Lockwood's ligament and the sheaths around the inferior rectus and inferior oblique muscles.<sup>17</sup> It passes upward and generally fuses with fibers of the orbital septum about 4–5 mm below the tarsal plate. From this junction, a common fascial sheet continues upward and inserts onto the lower border of the tarsus.

## Sympathetic Accessory Retractors

Smooth muscles innervated by the sympathetic nervous system are present in both the upper and lower eyelids and serve as accessory retractors.<sup>18</sup> In the upper eyelid, the supratarsal muscle of Müller originates abruptly from the undersurface of the levator muscle just anterior to Whitnall's ligament.<sup>19</sup> It runs downward, posterior to the levator aponeurosis and inserts onto the anterior edge of the superior tarsal border. In the lower eyelid, the sympathetic muscle is not as well defined. Fibers run behind the capsulopalpebral fascia to insert 2–5 mm below the tarsus.<sup>20</sup>

## Tarsal Plates

The tarsal plates consist of dense, fibrous tissue 1–1.5 mm thick that imparts structural integrity to the eyelids. Each plate measures about 25 mm horizontally and is curved gently to conform to the contour of the anterior globe; the central height of the tarsal plates is 8–12 mm in the upper eyelid and 3.5–4 mm in the lower. Medially and laterally they taper to 2 mm in height as they pass into the canthal tendons. Within each tarsus are the meibomian glands, numbering about 25 in the upper lid and 20 in the lower lid. These are holocrine-secreting sebaceous glands that are not associated with lash follicles. They produce the lipid layer of the precorneal tear film.

## Canthal Tendons

The medial canthus provides a number of important support structures that maintain alignment and orientation of the medial eyelids and allow for stability of the medial rectus muscle.<sup>21</sup> Medially, the tarsal plates pass into fibrous bands that form the crura of the medial canthal tendon. These lie between the orbicularis muscle anteriorly and the conjunctiva posteriorly. The superior and inferior crura fuse to form a stout common tendon that inserts via three limbs (see Fig. 12.1.3). The anterior limb inserts onto the orbital process of the maxillary bone in front of and above the anterior lacrimal crest. It provides the major support for the medial canthal angle. The posterior limb arises from the common tendon near the junction of the superior and inferior crura and passes between the canaliculi. It inserts onto the posterior lacrimal crest just in front of Horner's muscle and directs the vector forces backward to maintain close approximation with the globe. The superior limb of the medial canthal tendon arises as a broad arc of fibers from both the anterior and posterior limbs. It passes upward to insert onto the orbital process of the frontal bone. The posterior head of the preseptal orbicularis muscle inserts onto this limb, and the unit forms the soft tissue roof of the lacrimal sac fossa. This extension provides vertical support to the canthal angle<sup>22</sup> and appears to play a role in the lacrimal pump mechanism.

Lateral canthal anatomy is somewhat analogous to that of the medial canthus, but in general its support structures are less defined and less complex.<sup>23</sup> Laterally, the tarsal plates pass into not very well-developed fibrous strands that become the crura of the lateral canthal tendon. This is a distinct entity separate from the orbicularis muscle; it measures about 1 mm in thickness, 3 mm in width, and approximately 5–7 mm in length.<sup>24</sup> The insertion of these fibrous strands extends posteriorly along the lateral orbital wall, where it blends with strands of the lateral check ligament from the sheath of the lateral rectus muscle.

## Conjunctiva

The conjunctiva is a mucous membrane that covers the posterior surface of the eyelids and the anterior pericorneal surface of the globe. The palpebral portion is applied closely to the posterior surface of the tarsal plate and the sympathetic tarsal muscle of Müller. It is continuous around the fornices above and below, where it joins the bulbar conjunctiva. Small accessory lacrimal glands are located within the submucosal connective tissue.

## MOTOR NERVES

**Fig. 12.1.4 Motor Nerve Supply to the Eyelids: The Facial Nerve.** (Adapted with permission from Dutton JJ. Atlas of clinical and surgical orbital anatomy. 2nd ed. London: Elsevier Saunders; 2011. p. 155.)

A small mound of tissue, the caruncle, is at the medial canthal angle. The caruncle consists of modified skin that contains fine hairs, sebaceous glands, and sweat glands. Just lateral to the caruncle is a vertical fold of conjunctiva, the plica semilunaris.

## Nerves to the Eyelids

The facial nerve (seventh cranial nerve) is a unique structure that provides motor innervation to the muscle of facial expression and also contains special and general visceral efferent and special and general somatic afferent fibers. It has a complex anatomical relationship to the parotid gland.<sup>25</sup> The motor nerves to the periorbital muscles originate in the temporal and zygomatic branches (Fig. 12.1.4). These branches innervate the frontalis and orbicularis muscles, respectively. The buccal, mandibular, and cervical branches innervate muscles of the lower face and neck.<sup>26</sup>

The sensory nerves to the eyelids derive from the ophthalmic and maxillary divisions of the trigeminal nerve (Fig. 12.1.5). Sensory input from the upper lid passes to the ophthalmic division primarily through its main terminal branches, the supraorbital, supratrochlear, and lacrimal nerves. The infratrochlear nerve receives sensory information from the extreme medial portion of both upper and lower eyelids. The lower eyelid sends sensory impulses to the infraorbital nerve. The zygomaticofacial branch from the maxillary nerve innervates the lateral portion of the lower lid, and part of the infratrochlear branch receives input from the medial lower lid.

## Vascular Supply of the Eyelids

Vascular supply to the eyelids is extensive. The posterior eyelid lamellae receive blood through the vascular arcades. In the upper eyelid, a marginal arcade runs about 2 mm from the eyelid margin, and a peripheral arcade extends along the upper border of the tarsus between the levator aponeurosis and Müller's muscle (Fig. 12.1.6). These arcades are supplied medially by the superior medial palpebral vessels from the terminal ophthalmic artery and laterally by the superior lateral palpebral vessel from the lacrimal artery. The lower lid arcade receives blood from the medial and lateral inferior palpebral vessels.

The venous drainage system is not as well defined as the arterial system. Drainage is mainly into several large vessels of the facial system (see Fig. 12.1.6). Lymphatic drainage from the eyelids is restricted to the region anterior to the orbital septum. Traditional teaching is that lymphatic flow from the lateral two-thirds of the upper eyelid and the lateral one-third of the lower eyelid drain laterally into the deep and superficial parotid nodes, and flow from the medial one-third of the upper eyelid and the medial two-thirds of the lower eyelid drains inferiorly into the submandibular

and anterior cervical nodes. However, recent studies have shown a more diffuse drainage from all areas of the eyelids into the parotid nodes.<sup>27</sup>

# Clinical Anatomy of the Orbit

Jonathan J. Dutton

## 12.2

**Definition:** The orbit is the anatomical space bounded by the orbital bones and enclosed within the multilamellar periorbita.

### Key Features

- Anteriorly the orbit is limited by the orbital septum, which represents the anteriormost layer of the orbital septal system and separates the orbit from the eyelids.
- The orbit contains the eye and extraocular muscles, along with the nerves, vascular elements, and connective tissue support systems that subserve the visual system.

### INTRODUCTION

An understanding of orbital disease demands a clear concept of normal orbital anatomy and physiological function.<sup>1</sup> Only with this foundation can the clinician identify and characterize pathological states. In addition, the development of better surgical techniques requires a comprehensive knowledge of the structural relationships among the numerous anatomical systems that are crowded into the small space available.<sup>2</sup>

### GENERAL ORGANIZATION

The human orbit is a small cavity that has the approximate shape of a pear. Within this space is a complex array of closely packed structures, most of which subserve visual function.<sup>3,4</sup> Lobules of orbital fat surrounded by connective tissue fascia completely fill the spaces between the muscles, nerves, and vascular elements. The entire anatomical region is bound together into a functional unit, the complexity and precision of which are unmatched elsewhere in the vertebrate body.

### OSTEOLOGY OF THE ORBIT

Orbital bones arise from a complex series of primary or secondary ossifications around the evolving optic cup and stalk. Initially, the optic vesicles are positioned 170°–180° apart on opposite sides of the forebrain. Later these begin to rotate anteriorly as the primordial orbital bones are laid down around them.<sup>5</sup>

In adults, the bony orbit encloses a volume of about 30 cm<sup>3</sup>. It is composed of seven bones (Box 12.2.1). Except for a series of canals, fissures, and foramina that communicate with extraorbital compartments, the orbit is a closed compartment with a broad opening anteriorly (Fig. 12.2.1).

### Orbital Roof

The orbital roof is composed of the orbital plate of the frontal bone with a small contribution from the lesser wing of the sphenoid bone at the apex. This bone is a thin lamina that separates the orbit from the frontal sinus

anteriorly and from the anterior cranial fossa posteriorly. The roof slopes backward and downward from the orbital rim toward the apex and the optic canal. The optic canal measures 5–6 mm in diameter and 8–12 mm in length; it is oriented posteromedially about 35° to the midsagittal plane and upward about 38° to the horizontal plane.

### Lateral Orbital Wall

The lateral wall is formed by the greater wing of the sphenoid bone posteriorly and by the zygomatic process of the frontal bone and the orbital process of the zygomatic bone anteriorly.<sup>6</sup> It lies at a nearly 45° angle to the midsagittal plane. The lateral wall is bounded below by the inferior orbital fissure and medially by the superior orbital fissure. The convoluted frontozygomatic suture line runs approximately horizontally and crosses the superotemporal rim near the lacrimal gland fossa.

The lateral wall contains two areas of thickened bone, the posterolateral trigone in the sphenoid bone and the inferolateral basin in the zygomatic bone. Thinning of these regions has become an important component of balanced medial–lateral wall decompression surgery.<sup>7</sup>

### Orbital Floor

The floor is the shortest of the orbital walls; it extends back only 35–40 mm from the inferior rim. The orbital floor is composed primarily of the

**Fig. 12.2.1 Bony Anatomy of the Orbit in Frontal View.** (Redrawn with permission from Dutton JJ. Atlas of clinical and surgical orbital anatomy. 2nd ed. London: Elsevier Saunders; 2011. p. 22.)

#### BOX 12.2.1 Bones of the Orbit

- |                |                |
|----------------|----------------|
| Ethmoid bone   | Palatine bone  |
| Frontal bone   | Sphenoid bone  |
| Lacrimal bone  | Zygomatic bone |
| Maxillary bone |                |

maxillary bone; the zygomatic bone forms the anterolateral portion, and the palatine bone lies at the posterior extent of the floor. The orbital floor is thinnest just medial to the infraorbital canal, which is the most common site for blowout fractures. The orbital floor shows the greatest degree of deformation when external force is applied,<sup>8</sup> which explains the high rate of floor fractures associated with even minor degrees of blunt trauma.

The infraorbital groove begins at the inferior orbital fissure and runs forward in the maxillary bone. Within this canal runs the maxillary division of the trigeminal nerve and the maxillary artery. These exit just below the central orbital rim at the infraorbital foramen.

The floor is separated from the lateral orbital wall by the inferior orbital fissure, which is approximately 20 mm in length and runs in an anterolateral to posteromedial direction. The inferior fissure transmits structures into the orbit from the pterygopalatine fossa posteriorly and from the infratemporal fossa anteriorly.

## Medial Orbital Wall

The medial walls of the orbits are approximately parallel to each other and to the midsagittal plane. The medial wall is composed largely of the thin lamina papyracea of the ethmoid bone. This plate is exceptionally fragile, measuring only 0.2–0.4 mm in thickness. The lamina papyracea offers little resistance to expanding ethmoid sinus mucocoeles and commonly transmits inflammatory and infectious processes from sinusitis into the orbit.

Posterior to the ethmoid bone, the body of the sphenoid bone completes the medial wall to the apex.<sup>6</sup> The medial wall ends at the optic foramen, where the sphenoid forms the medial wall of the optic canal.

Within the frontoethmoid suture line in the superomedial orbit are the anterior and posterior ethmoidal foramina. The former usually lies 20–25 mm behind the anterior lacrimal crest and the latter about 32–35 mm behind the anterior crest and 5–10 mm anterior to the optic canal.<sup>9,10</sup> These foramina transmit branches of the ophthalmic artery and nasociliary nerve into the ethmoid sinus and nose. These vessels frequently are injured in orbital trauma and are the major sources of subperiosteal hematomas. These openings mark the approximate level of the roof of the ethmoid labyrinth and the floor of the anterior cranial fossa. The cribriform plate may lie up to 10 mm below this level, just medial to the root of the middle turbinate, and can be fractured during medial wall surgery.

Anterior to the ethmoid is the lacrimal bone, a thin plate that contains the posterior lacrimal crest and forms the posterior half of the lacrimal sac fossa. A summary of the orbital bones is given in [Box 12.2.2](#).

## CONNECTIVE TISSUE SYSTEM

In the human, an extensive system of connective tissue forms a framework for compartmentalization and support of all orbital structures.<sup>10,11</sup> It is essential to maintain the appropriate anatomical relationships between structural components.<sup>12–16</sup> Some connective tissue septa are aligned with directions of force that resist displacement of extraocular muscles during contraction. Others suspend and support delicate orbital vascular and neural elements. The essential components of this system include the periorbita, the orbital septal systems, and Tenon's capsule.<sup>17,18</sup>

### BOX 12.2.2 Orbital Bones Contributing to Each Wall

#### Roof

- Frontal bone

#### Floor

- Maxillary bone
- Zygomatic bone
- Palatine bone

#### Lateral Wall

- Zygomatic bone
- Greater wing of the sphenoid bone

## Periorbita

The orbit is lined with periosteum that is loosely adherent to the underlying orbital bones. Applied to the inner surface of the periosteum are multiple layers of orbital connective tissue that are continuous with the transorbital septal systems. Together this complex layer is known as the periorbita.

Within the orbit, the periorbita serves to support the extensive septal systems and to stabilize anatomical structures. At the orbital rim the inner layers of the connective tissue system separate from periosteum at the arcus marginalis and extend into the eyelids as the orbital septum. Thus the septum represents the anteriormost boundary of the orbital compartment.

## Orbital Septal System

Suspended from the periorbita to form a complex radial and circumferential web of interconnecting slings are connective tissue septa.<sup>12–15</sup> These septa form fine capsules around fat lobules and also surround the extraocular muscles, optic nerve, and neurovascular elements. The fascial slings provide support and maintain constant spatial relationships between these structures during ocular movements.<sup>19</sup> These septa are responsible for the transmission of restrictive forces from incarcerated extraocular muscles after trauma even in the absence of true muscle entrapment.

The anterior fascial system of the orbit primarily supports the globe, anterior orbital structures (such as the lacrimal gland and superior oblique tendon), and the eyelids. It consists of a number of well-developed condensations and ligaments. These structures include Lockwood's inferior ligament, Whitnall's superior suspensory ligament, the lacrimal ligaments, and the intermuscular septum. They coordinate movements between the globe and eyelids and suspend the globe so that gaze movements occur around stable axes of rotation ([Fig. 12.2.2](#)).

The connective tissue system is best developed in the midorbit. Here it forms well-defined fascial slings and suspensory complexes associated with each of the extraocular muscles ([Fig. 12.2.3](#)).

## Tenon's Capsule

Tenon's capsule is a dense, elastic, and vascular connective tissue layer that surrounds the globe, except over the cornea, and invests the anterior

**Fig. 12.2.2 The Connective Tissue System in Cross-Sectional Frontal View Through the Anterior Orbit at the Level of Whitnall's Ligament.** (Adapted with permission from Dutton JJ. *Atlas of clinical and surgical orbital anatomy*. 2nd ed. London: Elsevier Saunders; 2011. p. 122.)

**Fig. 12.2.3 The Connective Tissue System in Cross-Sectional Frontal View Through the Midorbit.** (Adapted with permission from Dutton JJ. Atlas of clinical and surgical orbital anatomy. 2nd ed. London: Elsevier Saunders; 2011. p. 121.)

portions of the extraocular muscles. This structure begins at the perilimbal sclera anteriorly and extends around the globe to the optic nerve, where it blends with fibers of the dural sheath and sclera.

En route from the orbital apex to the globe, the extraocular muscles must penetrate Tenon's capsule. The four rectus muscles pierce this structure posterior to the equator of the eye. As they proceed forward, the muscles and their thin, fibrous sheaths become invested by sleeve-like extensions of Tenon's capsule, which run with them to their insertions.

## MUSCLES OF OCULAR MOTILITY

Six striated extraocular muscles are attached to the eye and provide for ocular movement.<sup>20</sup> The four rectus muscles arise posteriorly from the annulus of Zinn, a fibrous band that is continuous with the periorbita and dura at the optic foramen.<sup>21</sup> The muscles run forward from the annulus of Zinn, surrounded by a sheath continuous with the orbital fascial systems. These fascial systems help keep the muscles in proper alignment and minimize the vector shifts that would otherwise be associated with ocular movement (Fig. 12.2.4).<sup>22-23</sup>

The superior oblique muscle arises above the annulus of Zinn just superior and medial to the optic foramen. It runs forward along the superomedial orbital wall to the cartilaginous trochlea, through which its tendon slides before it turns sharply laterally to insert on the superoposterior aspect of the globe.<sup>24</sup>

The inferior oblique muscle arises anteriorly from a small depression just below and lateral to the lacrimal sac fossa. It passes laterally and slightly backward to insert on the inferoposterior surface of the globe near the macula. Along its course, the sheath of the inferior oblique muscle joins that of the inferior rectus muscle and Tenon's capsule just behind the orbital rim to form Lockwood's inferior suspensory ligament. The capsulopalpebral fascia extends anteriorly from this ligament to the inferior tarsal plate.

The levator palpebrae superioris muscle originates from the annulus of Zinn and lesser sphenoid wing. It runs forward along the orbital roof in close approximation to the superior rectus muscle. Near the orbital rim a horizontal condensation is seen within the muscle sheath to form the prominent transverse ligament of Whitnall. The latter fuses to the orbital

**Fig. 12.2.4 Extraocular Muscles.** Orbital muscles of ocular motility as seen in the coronal plane. (Adapted with permission from Dutton JJ. Atlas of clinical and surgical orbital anatomy. 2nd ed. London: Elsevier Saunders; 2011. p. 39.)

wall near the trochlea and around the lacrimal gland. Whitnall's ligament is an important suspensory structure for the superior orbit and eyelid and should not be cut. Anterior to Whitnall's ligament, the levator muscle passes into a thin, fibrous aponeurosis that turns inferiorly and fans out into the eyelid. It inserts onto the inferior two-thirds of the anterior tarsal face.

## MOTOR NERVES OF THE ORBIT

The extraocular muscles are innervated by the third, fourth, and sixth cranial nerves.<sup>25</sup> The oculomotor nerve (third cranial nerve) enters the orbit via two branches. The superior branch innervates the superior rectus and levator muscles. The inferior branch sends fibers to the inferior rectus, medial rectus, and inferior oblique muscles. With the inferior division of the oculomotor nerve run parasympathetic fibers that arise from the Edinger–Westphal subnucleus. These synapse in the ciliary ganglion just lateral and inferior to the optic nerve at 1.5–2 cm behind the globe.<sup>26</sup> They progress via the short ciliary nerves to the ciliary body and iris sphincter. Little redundancy occurs to these nerves, so they may be injured easily during orbital dissection. This results in disturbances of pupillary function and accommodation.

The trochlear nerve (fourth cranial nerve) enters the extraconal space of the superior orbit through the superior orbital fissure above the annulus of Zinn. Here it crosses over the superior rectus and levator muscle complex and runs along the external surface of the superior oblique muscle before penetrating its substance in the posterior third of the orbit. In this position against the orbital roof, the trochlear nerve is damaged easily during blunt trauma.

The abducent nerve (sixth cranial nerve) enters the intraconal space of the orbit through the superior orbital fissure and annulus of Zinn. The nerve runs laterally to supply the lateral rectus muscle.

Sympathetic nerves enter the orbit via a number of different pathways to innervate the vascular muscular walls, the iris, and the accessory eyelid retractor muscles of Müller (Fig. 12.2.5).<sup>27</sup>

## SENSORY NERVES OF THE ORBIT

The optic nerve is technically not a sensory nerve but a central nervous system tract that arises from the retinal ganglion cells. The orbital portion

of the nerve is redundant to allow for ocular movement. It measures about 3 cm in length and takes a sinusoidal path from the globe to the optic canal. In close approximation to the nerve are the ophthalmic artery near the orbital apex and the superior ophthalmic vein in the midorbit. Both these vessels lie superior to the nerve in most individuals. The central retinal artery runs along the inferolateral side of the nerve to enter the dura about 1 cm behind the globe. The short and long posterior ciliary arteries lie close to the nerve for much of its length and are highly convoluted and redundant near the globe.

Sensory innervation to the orbit is primarily from the ophthalmic division of the trigeminal nerve (fifth cranial nerve) (Fig. 12.2.6). The maxillary division supplies portions of the inferior orbit. The ophthalmic division divides into branches in the cavernous sinus just as it passes into the superior orbital fissure.<sup>28</sup> The lacrimal nerve enters above the annulus of Zinn and proceeds along the superolateral orbit to the lacrimal gland and upper eyelid. The frontal nerve runs forward between the levator muscle and the orbital roof and exits the orbit at the supraorbital notch. At about the level of the posterior globe, it gives rise to the supratrochlear nerve, which exits the orbit at the superomedial rim.

The nasociliary nerve is a branch of the ophthalmic division that enters the orbit through the superior orbital fissure and annulus of Zinn. It crosses from lateral to medial over the optic nerve after sending small sensory branches that pass through the ciliary ganglion without synapse and continue to the globe with the short ciliary nerves. As it passes to the medial side of the optic nerve, the nasociliary nerve gives off the long posterior ciliary nerves, which extend to the posterior globe. The nasociliary nerve continues forward and exits at the superomedial rim as the infratrochlear nerve.

Recent studies have shown complex neural connections between the trigeminal nerve and motor nerves to the extraocular muscles in the cavernous sinus and in the posterior orbit. It is not clear whether these are all sensory, or some combination of sensory and sympathetic nerves.<sup>29</sup>

## ARTERIAL SUPPLY TO THE ORBIT

The arterial supply to the orbit arises from the internal carotid system through the ophthalmic artery, with anastomotic connections to the external carotid system through the superficial facial vessels.<sup>30</sup> The ophthalmic artery enters the orbit through the optic canal inferotemporal to the optic

**Fig. 12.2.5 Motor Nerves of the Orbit That Serve the Muscles of Ocular Motility, in Coronal View.** (Adapted with permission from Dutton JJ. *Atlas of clinical and surgical orbital anatomy*. 2nd ed. London: Elsevier Saunders; 2011. p. 67.)

nerve (Fig. 12.2.7). In about 83% of individuals, the vessel crosses over the nerve to the medial side of the orbit; in the remaining 17%, it crosses below the nerve.<sup>31</sup> Shortly after it enters the orbit, the ophthalmic artery gives off a number of branches, with some variability in the sequence between individuals. The central retinal artery is usually the first branch. It runs along the inferior aspect of the optic nerve to penetrate the dura anywhere from

8–15 mm behind the globe. The lacrimal artery generally arises next and gives rise to the zygomaticotemporal artery, which penetrates the lateral wall at about the midorbit, and to the zygomaticofacial artery, which runs inferolaterally to exit through a small foramen in the zygomatic bone. The lacrimal artery terminates in the lids as the lateral inferior and superior palpebral arteries.

As the ophthalmic artery passes toward the medial orbit, the supraorbital branch is given off. This passes through the intermuscular septum medial to the levator muscle and runs forward with the frontal nerve to the supraorbital notch. In the medial orbit, the ophthalmic artery gives rise to the posterior and anterior ethmoidal arteries, which enter the ethmoidal foramina.<sup>32,33</sup> The ophthalmic artery then continues forward to exit just above the medial canthus as the dorsal nasal artery. Here, it gives off the inferior and superior medial palpebral arteries. The branching order is summarized in Box 12.2.3.

## VENOUS DRAINAGE FROM THE ORBIT

Venous drainage from the orbit is primarily through the superior and inferior ophthalmic veins (Fig. 12.2.8).<sup>34–36</sup> The superior ophthalmic vein

**Fig. 12.2.6 Sensory Nerves of the Orbit, in Lateral View.** (Adapted with permission from Dutton JJ. *Atlas of clinical and surgical orbital anatomy*. 2nd ed. London: Elsevier Saunders; 2011. p. 73.)

### BOX 12.2.3 Most Common Branching Order of the Ophthalmic Artery

1. Central retinal artery
2. Lateral posterior ciliary artery
3. Lacrimal artery
4. Muscular branch to superior rectus and levator muscles
5. Posterior ethmoidal and supraorbital arteries
6. Medial posterior ciliary artery
7. Muscular branch to medial rectus muscle
8. Muscular branch to superior oblique muscle
9. Branch to connective tissue
10. Anterior ethmoidal artery
11. Inferior medial palpebral artery
12. Superior medial palpebral artery
- T1. Dorsal nasal artery
- T2. Supratrochlear artery

**Fig. 12.2.7 Arterial Supply to the Orbit, in Coronal View.** (Adapted with permission from Dutton JJ. *Atlas of clinical and surgical orbital anatomy*. 2nd ed. London: Elsevier Saunders; 2011. p. 93.)

**Fig. 12.2.8 Orbital Veins.** Venous drainage from the orbit, in coronal view. (Adapted with permission from Dutton JJ. *Atlas of clinical and surgical orbital anatomy*. 2nd ed. London: Elsevier Saunders; 2011. p. 103.)

originates at the superomedial orbital rim from branches of the angular, supratrochlear, and supraorbital veins.<sup>37,38</sup> As it passes backward along the medial orbit, it is joined by branches draining the medial and superior rectus muscles and the levator muscle and by the superior vortex veins, the anterior ethmoidal vein, and collateral branches from the inferior ophthalmic vein.<sup>39</sup> At about the midorbit it crosses to the lateral orbit just below the superior rectus muscle. Here it is joined by the lacrimal vein and continues posteriorly to enter the cavernous sinus through the superior orbital fissure.<sup>40</sup>

The inferior ophthalmic vein has an indistinct origin in a plexus of small vessels in the inferior orbit. It passes backward along the inferior rectus muscle and is joined by branches draining the inferior rectus and inferior oblique muscles, the inferior vortex veins, and the lateral rectus muscle.

# Orbital Imaging

Jonathan J. Dutton

## 12.3

### Definitions:

- Computed tomography: An imaging technique where contrast differences are based on tissue density based on the passage of x-rays through tissues.
- Magnetic resonance imaging: An imaging technique where density differences are based on tissue proton density and their resonance characteristics based on biochemical relationships within the atomic lattice.
- Orbital pathological processes often have characteristic features that can help narrow the diagnostic possibilities when considered in combination with the clinical findings.

### Key Features

- Orbital CT is the imaging procedure of choice for evaluation of bony detail.
- Magnetic resonance imaging has become the most important technique for most orbital lesions, for the optic nerve, and for the orbital apex, where it can distinguish tissues based on their biochemical differences.

## INTRODUCTION

Orbital pathology often presents a challenge in making an accurate diagnosis. Radiographic examination is an essential step in the evaluation of all patients who have suspected orbital disease, and it can help narrow the differential diagnosis. Although imaging can contribute significant information, pertinent clinical input is necessary for adequate radiographic interpretation.<sup>1</sup> Imaging patterns and features can often point to specific diagnostic possibilities compared with expected normal anatomy.<sup>2</sup> Orbital imaging can also may help the physician plan the most appropriate medical therapy or surgical approach.<sup>3-6</sup> Computed tomography (CT) and magnetic resonance imaging (MRI) have largely replaced older techniques (Fig. 12.3.1). MRI in particular has proven valuable in delineating orbital strictures including blood vessels, nerves, and connective tissue septae.<sup>7-9</sup>

## NORMAL ORBITAL ANATOMY IN THE AXIAL PLANE

### Axial Section Through the Lowermost Orbit

The axial plane is horizontal through the orbit, perpendicular to the cephalocaudal axis of the body. The orbital floor appears as a thin, oblique density that runs from anteromedial to posterolateral, separating the orbit from the maxillary sinus.<sup>10,11</sup> Because the floor gradually slopes backward and upward, successively higher cross-sections are cut in axial scan sequences. The orbital cavity is bounded medially by the anterior lacrimal crest and laterally by the lateral rim of the zygomatic bone. Posterior to the orbit is the cranial base.<sup>12</sup> A thin line arches across the orbital opening from the medial to the lateral bony rims; this represents the lower eyelid and orbital septum.<sup>3</sup>

Depending on the level of the cut, the orbital cavity may appear empty (because it contains only orbital fat) or it may contain a rounded density that represents the sclera cut tangentially. Occasionally the inferior oblique muscle is seen as an oblique band of medium-density tissue, and in slightly higher sections, the inferior rectus muscle may appear as a density adjacent to the globe posteriorly.

### Axial Section Through the Inferior Orbit

In low axial sections through the inferior orbit, the floor again appears as a thin density that separates the orbital cavity from the maxillary sinus. In the posterolateral corner of the orbit, where the floor approaches the lateral wall, a channel separates the body of the sphenoid bone from the greater wing. This is the inferior orbital fissure. Posteriorly, behind the inferior rectus muscle, this fissure communicates between the orbital space and the pterygopalatine fossa. In the anteromedial corner of the orbit, the lacrimal sac fossa is seen as a depression in the orbital process of the maxillary bone.

Within the orbital space, a central, rounded density represents the globe. Because the vitreous is primarily aqueous, it appears empty (black) on CT. On MRI scans, the vitreous appears dark on T1-weighted sequences and bright on T2-weighted sequences. Just posterior to the globe is a rounded density that lies on the midportion of the orbital floor and is discontinuous with the globe. This is the inferior rectus muscle cut in cross-section.

Fig. 12.3.1 Axial Computed Tomography of the Orbits. (A) Tissue density window. (B) Bone density window.

## Axial Section Through the Midorbit

On axial scans through the midorbit, the globe is seen in equatorial section (Figs. 12.3.2 and 12.3.3). Anteriorly, the lens is seen as an oval density. On MRI sections, the ciliary body can be distinguished on either side of the lens.<sup>3</sup> Behind the globe, the optic nerve is seen to emerge from the posterior sclera and run toward the orbital apex.<sup>13,14</sup>

In the midorbit, a gently curved enhancing line crosses the orbit from lateral to medial. This is the superior ophthalmic vein.<sup>15</sup> Near the orbital apex, a small enhancing vessel is seen to cross over the optic nerve from lateral to medial. This is the second portion of the ophthalmic artery. Along the orbital walls are the lateral and medial rectus muscles. At slightly higher levels, both the medial rectus and superior oblique muscles are often seen together. On either side of the midline are the ethmoid sinuses, with the thin lamina papyracea that forms the medial orbital wall. Just medial to the laminae are the ethmoid air cells.

## Axial Section Through the Superior Orbit

At this level, the orbital contour is narrower and terminates posteriorly in a rounded angle above the level of the optic canals. Within the orbital outline,

**Fig. 12.3.2 Axial CT Scan Through the Midorbit.** The globe and optic nerve are seen in the axial plane, along with the medial and lateral rectus muscles. E, Ethmoid sinus; LR, lateral rectus; MR, medial rectus; ON, optic nerve; S, sphenoid sinus.

**Fig. 12.3.3 Axial MRI Scan Through the Midorbit.** The section is slightly higher than in Fig. 12.3.2. The optic nerves are seen passing back to the optic chiasm. E, Ethmoid sinus; LR, lateral rectus; MR, medial rectus; ON, optic nerve; S, sphenoid sinus.

the globe is represented in cross-section above the level of the lens. Along the medial wall is the superior oblique muscle that passes through the trochlea anteromedially. Near the orbital apex, the superior rectus muscle appears as a broad band of tissue directed toward the globe. The superior ophthalmic vein is seen as a curvilinear enhancing structure that crosses from anteromedial to posterolateral just below the muscle. Anterolaterally, near the lateral orbital rim, the lacrimal gland appears as an oval density seen between the zygomatic bone and the globe.

## Axial Section Through the Orbital Roof

In axial sections above the level of the globe, the orbit appears as a rounded contour posteriorly. Because the roof lies in a plane oblique to the tissue slice, in each higher section the roof lies progressively more anteriorly as it approaches the orbital rim. The levator muscle is seen as a broad band that extends from the superior orbital rim backward along the roof. Anteromedially, the trochlea is seen clearly, and at appropriate levels the superior oblique tendon can be visualized as it fans out over the superior globe below the superior rectus muscle insertion.

## NORMAL ORBITAL ANATOMY IN THE CORONAL PLANE

### Coronal Section Through the Antermost Orbit

The coronal plane is vertical, passing through the orbit parallel to the left-right axis. The sagittal plane is vertical but in an anterior-posterior direction. In coronal sections through the anteriormost orbit, the globe is cut through the level of the eyelids. The frontal sinus is in the midline of the orbital roof, below the frontal lobes of the brain. The anterior segment of the globe may appear as several concentric densities that represent the cornea, lens, and anterior sclera. In the superior medial corner of the orbit are the trochlea and tendon of the superior oblique muscle. Inferiorly, the inferior oblique muscle can be seen as a linear shadow that runs from the inferomedial orbital wall toward the lateral orbit.

### Coronal Section Through the Anterior Orbit

Sections that cut through the anterior midorbit pass through the globe near its equator. At this level, the orbital roof is seen as a thin, curved plate of bone with an upper surface that undulates against the overlying frontal lobes. In the midline is the crista galli, and on either side are the cribriform plate and roof of the ethmoid sinus.

The orbital floor is a thin plate of bone that extends from the lowermost extent of the lamina papyracea and slopes downward and laterally to the inferolateral orbital wall. Immediately below the floor is the triangular maxillary sinus.

Centrally, the globe is seen to fill most of the orbital space (Figs. 12.3.4 and 12.3.5). Superiorly, the thin superior rectus muscle lies adjacent to the globe, and above it is the levator muscle. Medially, the flattened medial rectus muscle lies within the orbital fat between the lamina papyracea and

**Fig. 12.3.4 Coronal CT Scan Through the Anterior Portion of the Orbit.** The globes are cut in cross-section, and the rectus muscles are seen as flattened densities near the sclera. IR, Inferior rectus; LM, levator muscle; LR, lateral rectus; MR, medial rectus; SR, superior rectus.

**Fig. 12.3.5 Coronal MRI Scan Through the Anterior Portion of the Orbit.** The cut is similar to that seen in Fig. 12.3.4. IR, Inferior rectus; LM, levator muscle; LR, lateral rectus; MR, medial rectus; SR, superior rectus.

**Fig. 12.3.6 Coronal CT Scan Through the Midorbit.** The optic nerve lies centrally, surrounded by the rectus muscles. Just below the lateral edge of the superior rectus is the superior ophthalmic vein. ON, Optic nerve; SOV, superior ophthalmic vein; SR, superior rectus muscle.

the globe. Just below the eye is the inferior rectus muscle, and laterally is the lateral rectus muscle. In the superomedial corner, a small, round shadow is the superior oblique muscle. At the medial edge of the superior rectus–levator muscle complex is a round enhancing structure, the superior ophthalmic vein.

### Coronal Section Through the Central Orbit

In coronal sections behind the globe, the orbital walls appear as in more anterior sections. Within the central space of the orbit lies the round optic nerve cut in cross-section (Figs. 12.3.6 and 12.3.7). On MRI scans, the central nerve can easily be distinguished from the nerve sheaths; the two are separated by the clear subarachnoid space. The four rectus muscles are seen against their respective orbital walls cut across their midbellies. The levator muscle appears as a separate thin strap just above and medial to the superior rectus. Above the medial rectus muscle, along the superomedial corner of the orbit, is the superior oblique muscle. The superior ophthalmic vein is a small, enhancing circular density between the optic nerve and the superior rectus muscle en route to the lateral orbit.

### Coronal Section Through the Anterior Orbital Apex

Toward the apex, the bony orbit narrows to a triangular section. Inferolaterally, the contour opens into the inferior orbital fissure that communicates

**Fig. 12.3.7 Coronal MRI Scan Through the Midorbit.** Structures are similar to those observed in Fig. 12.3.6. LR, Lateral rectus muscle; MR, medial rectus muscle; ON, optic nerve; SR, superior rectus muscle.

with the infratemporal fossa. Within the orbit, the optic nerve, the superior oblique muscle, and all four rectus muscles can still be identified as separate structures. The superior ophthalmic vein is found more laterally, to the lateral edge of the superior rectus muscle. The ophthalmic artery is seen just above the optic nerve as it crosses over the nerve from lateral to medial.

### Coronal Section Through the Posterior Orbital Apex

At this level, the orbit is reduced to a small, rounded space, open inferiorly to the pterygopalatine fossa. It is bounded laterally by the greater wing of the sphenoid and medially by the body of the sphenoid adjacent to the sphenoid sinus. Superolaterally, the orbit opens into the middle cranial fossa through the superior orbital fissure.

## Computed Tomographic Imaging Features of Some Orbital Pathologies<sup>1</sup>

### Cavernous Hemangioma

These vascular tumors appear as a well-defined, oval to round, homogeneous mass with a density somewhat greater than muscle. It is typically located in the intraconal space, but when large they can extend extraconally. Long-standing larger lesions can cause bone remodeling, and small foci of calcium can sometimes be seen. Enhancement is usually mild to moderate because of its generally low vascular blood flow.

### Dermoid Cyst

Usually located at the superotemporal orbital rim, dermoid cysts are typically round to oval well-defined cystic lesions. The internal signal is low when the fat content is high, and a fat-fluid level may be seen. Dense foci within the cyst represent flecks of keratin and sebum. The cyst is surrounded by a denser enhancing wall that may be partially calcified. The adjacent orbital rim may show remodeling or the cyst may be embedded within the bone.

### Thyroid Eye Disease

The CT scan reflects some of the key clinical findings of this disease, proptosis and increased orbital fat. Multiple extraocular muscles in one or both orbits are enlarged with sparing of the muscle insertions. The inferior and medial rectus muscles are most commonly involved. The superior ophthalmic vein may be enlarged from orbital congestion, and the optic nerve is rarely compressed by enlarged muscle at the apex.

### Optic Nerve Sheath Meningioma

With this tumor of the nerve sheath the optic nerve typically shows a smooth tubular enlargement, but rarely may be exophytic when it breaks

through the dura. In 20%–50% of cases there may be foci of calcification. With contrast there is marked enhancement of the tumor with a central zone of low attenuation representing the optic nerve. This is the so-called tram-track sign. With more posterior lesions the optic canal can be enlarged.

### **Myositis**

One or sometimes several extraocular muscles show a somewhat diffuse enlargement that may have irregular and shaggy borders. Density is usually greater than normal muscle and unlike thyroid orbitopathy the tendon of insertion is frequently also enlarged.

### **Optic Nerve Glioma**

In the orbit gliomas typically appear as a well-outlined fusiform enlargement of the optic nerve, but they may be globular in some cases. The nerve may show tortuosity or kinking and is usually heterogeneous in density. Low-density cystic spaces correspond to areas of mucinous degeneration. Enhancement varies from imperceptible to moderate. The tumor may extend back to the optic chiasm and occasionally along the optic radiations.

### **Adenoid Cystic Carcinoma**

CT shows a heterogeneous mass centered in the lacrimal gland fossa. It can be irregular and poorly demarcated or round and well outlined. It can extend along the lateral rectus muscle and the lateral orbital wall to the orbital apex. Destruction of adjacent bone is common, especially

with larger tumors. With contrast there are often areas of marked focal enhancement.

### **Orbital Mucocele**

There is usually opacification of one or more sinuses with extension of a sharply defined, rounded cystic mass into the adjacent orbit. The intervening bone may be destroyed or remodeled as a thin shell around the cyst. When large, orbital structures such as optic nerve and muscles are displaced laterally. The cyst contents are usually homogeneous and of low density when filled with mucoid material but can sometimes image as dense as muscle when more viscid. There is no enhancement with contrast.

# Blepharoptosis

Caroline W. Vargason, Jeffrey A. Nerad

## 12.4

**Definition:** Ptosis is defined as the upper eyelid resting in a droopy, abnormally low position while the eye is in primary gaze.

### Key Features

- Blepharoptosis (ptosis) is caused by a weakness in one or both of the eyelid retractors, the levator muscle, and Müller's muscle, which position the upper eyelid.
- Ptosis can be broadly categorized into common and unusual types. Common types are acquired involutional ptosis and simple congenital ptosis.
- Ptosis presents with various symptoms, including decreased vision, brow ache, headache, difficulty reading, and neck ache.
- Surgery is considered in symptomatic patients or patients who are displeased with their droopy eyelid appearance.
- Ptosis repair surgery aims to elevate the eyelid position without causing excessive lagophthalmos.

### INTRODUCTION

Ptosis repair surgery has a storied history of trial and error. Surgical approaches date back to the ancient Arabians and have attempted to modify each anatomical component of the upper eyelid and brow, including superior rectus transposition to the eyelid.<sup>1</sup>

Modern surgical approaches are directed by levator function. Poor levator function requires correction by frontalis suspension. Dransart (1880) first described frontalis suspension with nonabsorbable sutures, and Wright (1922) popularized the fascia lata sling.<sup>1</sup> Good levator function allows correction by levator or Müller's muscle resection. Bowman (1957) described the first transconjunctival levator-Müller's muscle complex resection, and Jones et al. (1975) introduced the levator aponeurosis advancement operation performed today.<sup>1,2</sup> The posterior approach Fasanella-Servat Müller tarsectomy (1961) and Putterman's Müllerectomy (1975) are also used in patients with good levator function.<sup>3-5</sup>

### FOUNDATION: A SIMPLIFIED CLASSIFICATION OF PTOSIS

This simplified classification of ptosis has two main categories, *common ptosis* and *unusual ptosis*. A solid understanding of the two most common types of ptosis, acquired involutional ptosis and simple congenital ptosis, will allow you to recognize easily the uncommon types. [Box 12.4.1](#) lists the differential diagnosis for ptosis.

### Anatomy and Function

To understand ptosis, it is important to first appreciate normal anatomy. The normal upper eyelid rests at the upper limbus. The upper eyelid is opened by retractors, which are the levator, Müller's, and frontalis muscles. Because the levator muscle is the primary upper eyelid retractor, abnormalities in the levator complex are the cause of most ptosis. The levator muscles are innervated by the superior division of the oculomotor nerve and follow Hering's law of equal and simultaneous innervation.<sup>6,7</sup> Thus if ptosis is asymmetrical, and the more ptotic eyelid is lifted, any "extra" innervation to the less ptotic eyelid will disappear, causing that eyelid to drop.

Eyelid health can be assessed by measuring the three *eyelid vital signs*.<sup>8</sup>

- Margin reflex distance 1 (MRD<sub>1</sub>) is the measured distance from the central light reflex to the upper eyelid margin. A normal MRD<sub>1</sub> is 4–5 mm. A low MRD<sub>1</sub> defines ptosis.
- Levator function, which indicates the strength of the levator muscle, is the measured excursion of the upper eyelid margin from downgaze to upgaze with the brow immobilized. A normal levator function is at least 15 mm.
- The lid crease height and strength provide additional information about levator strength. *Levator pulling on the skin creates the skin crease*. Thus a weaker levator has less skin pull, creating a weaker or less distinct crease.

### Classification Based on Levator Function

*Levator function is the basis for classification and treatment of ptosis.* Adults with involutional ptosis will have normal or near-normal levator function and are treated with levator aponeurosis advancement surgery. Children with simple congenital ptosis will have reduced levator function and are treated with frontalis sling surgery. If your patient with ptosis does not fit into these categories—meaning an adult with much decreased levator function or a child with normal levator function—then you must consider other *unusual* diagnoses (see [Box 12.4.1](#)).

### Common Ptosis

Most older adults will have acquired involutional ptosis, and most children will have simple congenital ptosis. Although an oversimplification, this classification is a practical and helpful approach to assessing your ptosis patients.

### Acquired Involutional Ptosis

Most adults with acquired ptosis have involutional changes in the levator muscle and aponeurosis. The ptosis can be unilateral or bilateral ([Fig. 12.4.1](#)). Classically, the pathophysiology of involutional ptosis was described as aponeurotic dehiscence or disinsertion from the superior tarsus.<sup>2,9</sup> It was later found that most patients have an attached aponeurosis with

#### BOX 12.4.1 Differential Diagnosis of Upper Eyelid Ptosis<sup>8</sup>

##### Common Ptosis

- Acquired involutional ptosis—normal levator function
- Simple congenital ptosis—reduced levator function

##### Unusual Ptosis

###### Congenital

- Blepharophimosis
- Marcus Gunn jaw-winking

###### Acquired

- Neurogenic
  - Myasthenia gravis
  - Third cranial nerve palsy
  - Horner's syndrome
- Myogenic
  - Oculopharyngeal dystrophy
  - Myogenic dystrophy
  - Chronic progressive external ophthalmoplegia
- Posttraumatic

**Fig. 12.4.1 Acquired Involuntional Ptosis.** (A) Bilateral ptosis with a weak, high lid crease. (B) Normal levator function. (C) Weak lid crease and ptosis persist in downgaze. (D) Normal lid height after bilateral levator aponeurosis advancement surgery.

aponeurotic thinning or myogenic abnormalities.<sup>10–12</sup> Thus, involuntional ptosis can be aponeurotic, myogenic, or both.

It is helpful to think of the aponeurosis being “stretched” and the muscle having relatively normal function, as the *three key clinical features* conform to this idea. First, levator function measurement will be normal. Second, a high skin crease is present due to aponeurotic stretching and skin–levator muscle fiber attachment being located more superiorly. Third, lid drop on downgaze is present due to aponeurotic stretching resulting in a “longer” eyelid. Levator aponeurosis advancement surgery will correct the ptosis.

### Simple Congenital Ptosis

Most children with ptosis have simple congenital ptosis. It is present from birth and caused by *dystrophy of the levator muscle*, where fatty tissue infiltration weakens the muscle. *Simple* refers to the dystrophic levator muscle being the only ocular problem (except maybe strabismus and amblyopia)

**Fig. 12.4.2 Simple Congenital Ptosis.** (A) Bilateral upper eyelid ptosis with left much greater than right. Very weak left upper eyelid crease, indicating poor levator muscle function. (B) Left ptosis present in upgaze, again indicating poor levator muscle function. (C) Left lid lag, or ptosis reduction in downgaze, due to decreased excursion of the fibrotic levator muscle.

in an otherwise healthy child. The ptosis is usually bilateral and quite asymmetrical (Fig. 12.4.2). At least 65% of cases are reported as “unilateral” even though many of the so-called unilateral cases in reality have mild ptosis of their other eye.<sup>13,14</sup> Strabismus and amblyopia are more common in patients with congenital ptosis compared with the general pediatric population, emphasizing the importance of monitoring visual acuity and ocular motility in all patients with congenital ptosis.<sup>15–19</sup>

On examination patients will have *three typical findings* consistent with a weak, fibrotic levator muscle. First, levator function measurement will be reduced, as the weak muscle does not move well in upgaze. Second, a weak or absent skin crease is present due to the weak muscle pulling less on the skin. Third, lid lag on downgaze results from the weak muscle also not moving well in downgaze.

Early surgical intervention is indicated for visual axis obstruction. Surgical treatment is based on levator function. A frontalis sling operation is necessary for severe ptosis with poor levator function of less than 4 mm. For mild to moderate ptosis with at least 4 mm of levator function, tightening the levator with a levator resection operation is appropriate.<sup>20</sup>

## DIFFERENTIAL DIAGNOSIS

### Common Ptosis

The two most common types of ptosis, *simple congenital ptosis* and *acquired involuntional ptosis*, are reviewed earlier. A complete differential diagnosis is listed in Box 12.4.1. If the patient does not have common ptosis, the history and physical examination will guide you to diagnosis of an unusual type of ptosis.

**Fig. 12.4.3 Marcus Gunn Jaw-Winking Syndrome.** (A) Right upper eyelid ptosis in primary gaze with mouth closed. (B) Right upper eyelid elevates when the jaw is opened.

**Fig. 12.4.4 Blepharophimosis Syndrome.** (A) Symmetrical bilateral ptosis, epicanthus inversus, and telecanthus. (B) Postoperative appearance after bilateral frontalis sling placement and medial canthoplasty.

## Unusual Congenital Ptosis

### Marcus Gunn Jaw-Winking Syndrome

This ptosis results from “miswiring” between the mandibular branch of the fifth cranial nerve, innervating the pterygoid muscle, and the superior branch of the third cranial nerve, innervating the levator muscle. Resulting synkinesis causes the droopy eyelid to elevate when the mouth opens and can be unilateral or bilateral (Fig. 12.4.3).<sup>21</sup> All children with congenital ptosis should be examined for Marcus Gunn jaw-winking by asking them to eat or chew gum.

A broad range of abnormal synkinetic eyelid movement, or winking, occurs. The amount of winking is not necessarily proportional to ptosis or levator function.<sup>22</sup> Moderate 2–4 mm winking is most common, followed by mild, and then severe.<sup>23</sup> Patients with moderate to severe winking, severe ptosis, and poor levator function are treated with levator extirpation to eliminate the abnormal movement and a frontalis sling to elevate the eyelid.<sup>24</sup> Patients with minimal winking, mild ptosis, and good levator function are treated with levator resection. Many children learn to control mouth movements to minimize their winking.

### Blepharophimosis Syndrome

This congenital syndrome is characterized by *ptosis*, *epicanthus inversus*, and *telecanthus* and is inherited in an autosomal dominant pattern. Sporadic cases can also occur. Type I is associated with premature ovarian failure, where 70% have a mutation in the *FOXL2* gene, whereas type II is not.<sup>25,26</sup> Referral to a geneticist is recommended. The ptosis is bilateral and usually severe with poor levator function. Phimosis refers to the horizontal shortening of the lid aperture. Children have characteristic low-set ears and an elfish appearance (Fig. 12.4.4). Coincident amblyopia is more frequent than in simple congenital ptosis and more likely to occur with asymmetrical lid position.<sup>27,28</sup> Severe ptosis is treated with a frontalis sling. Additional reconstructive procedures can correct the epicanthal folds and telecanthus.

## Unusual Acquired Ptosis

Types of unusual acquired ptosis fit into three basic categories. First, neurogenic is a problem with innervation of levator or Müller’s muscle. Second, myogenic is a weakness of the muscle itself. Third, posttraumatic involves scarring of the levator muscle.

## Neurogenic Ptosis

### Myasthenia Gravis

Myasthenia gravis is an autoimmune disease in which antibodies against the neuromuscular junction cause a reduction in acetylcholine receptors, resulting in poor nerve conduction and weak muscles. Ptosis or diplopia are the presenting symptom in up to 85% of patients.<sup>29</sup> Few patients have ocular myasthenia, whereas up to 53% develop generalized myasthenia.<sup>30–32</sup> Most patients have autoantibodies to neuromuscular junction targets.<sup>33</sup>

Ptosis is characteristically *variable* and can be unilateral or bilateral. If a patient reports variable ptosis, examine for fatigability and Cogan’s lid twitch on sustained upgaze.<sup>34</sup> Diagnosis is made clinically and is confirmed classically with a Tensilon test (Fig. 12.4.5); this has fallen out of favor due to potential side effects. Ice pack testing, serum autoantibodies, and electromyography are currently used diagnostics.<sup>33,35</sup>

Medical treatment consists of oral cholinesterase inhibitors or immunosuppressive medications.<sup>36</sup> Thymectomy is beneficial in select patients.<sup>37</sup> Ptosis repair surgery is appropriate for patients with vision impairment after maximal medical treatment.<sup>38</sup> Surgical correction options are levator aponeurosis advancement or frontalis suspension, and levator function determines the operation choice.<sup>8</sup>

### Third Cranial Nerve Palsy

The third nerve can be damaged by trauma, ischemia, infection, tumor, or compression, causing ptosis and diplopia.<sup>39</sup> Congenital palsies are rare and usually do not cause diplopia.<sup>40</sup> Acquired palsies have varying degrees of nerve weakness and levator function and can be temporary. *Aberrant regeneration* of the third nerve often develops during recovery, resulting in gaze-evoked lid elevation.<sup>41,42</sup> Diplopia is generally more bothersome to patients than ptosis. After allowance for adequate time (6–12 months) for spontaneous recovery, strabismus surgery is performed before ptosis repair.<sup>39</sup> The ptotic eyelid can be elevated with a frontalis sling or levator aponeurosis advancement.

**Fig. 12.4.5 Myasthenia Gravis.** (A) Severe bilateral ptosis. (B) Improved bilateral ptosis after administration of Tensilon (edrophonium chloride 10 mg/mL).

**Fig. 12.4.6 Horner's Syndrome.** The right side is affected with ipsilateral upper eyelid ptosis and pupillary miosis. Note that the patient is elevating the right brow in attempt to compensate for the ptosis.

### Horner's Syndrome

Horner's syndrome is caused by sympathetic denervation to the face. Patients have ptosis, lower lid elevation, miosis, and ipsilateral facial anhidrosis. Ptosis results from denervation of Müller's muscle and thus is a *mild ptosis with preserved levator function* (Fig. 12.4.6). Heterochromia may be present with congenital Horner's syndrome. The ipsilateral iris is lighter.<sup>43</sup>

Pharmacological testing can diagnose and localize the Horner's lesion. Traditionally cocaine drops were used.<sup>44</sup> They have been replaced largely by apraclonidine, whose  $\alpha_1$  stimulation dilates the Horner's pupil and elevates the ptotic eyelid.<sup>45</sup> Hydroxyamphetamine stimulates norepinephrine release at the neuromuscular junction, reversing the signs of preganglionic Horner's.<sup>46,47</sup> Ptosis repair is indicated for visually significant ptosis or cosmesis. Levator resection and posterior Müllerectomy are both effective.<sup>48</sup>

### Myogenic Ptosis

#### Chronic Progressive External Ophthalmoplegias

Chronic progressive external ophthalmoplegia (CPEO) is a rare progressive myopathy presenting with symmetrical bilateral ptosis in early adulthood (Fig. 12.4.7) and later onset severe ophthalmoplegia.<sup>49</sup> Defects in mitochondrial function are inherited in mitochondrial, autosomal dominant, or autosomal recessive patterns.<sup>50</sup> Systemic involvement variants are termed "CPEO plus" syndromes.<sup>51</sup> Kearns-Sayre syndrome includes pigmentary retinopathy and cardiac conduction defects.<sup>52</sup> All patients with ptosis and

**Fig. 12.4.7 Chronic Progressive External Ophthalmoplegia (CPEO).** Severe bilateral ptosis with extraocular motility deficits. Note that the patient elevates both brow well, making frontalis suspension a possible surgical option.

motility defects should be referred for neurological evaluation. Muscle biopsy can confirm the diagnosis. Ptosis repair by frontalis suspension is appropriate only when vision becomes impaired. Additional surgery to elevate the lower lid is often needed to prevent dryness, as patients often have a weak orbicularis and poor Bell's reflex.<sup>8</sup>

### Oculopharyngeal Dystrophy

Oculopharyngeal dystrophy (OPD) is an autosomal dominant, progressive myopathy, predominantly found in patients of French Canadian ancestry. It presents in the fifth decade with symmetrical bilateral ptosis, dysphagia, and proximal limb weakness.<sup>53</sup> Abnormal filamental internuclear aggregates impair muscle function.<sup>54</sup> Ptosis repair by levator aponeurosis advancement is successful early in the disease course. To prevent a second operation, frontalis sling surgery should be considered earlier than usual for other types of ptosis.<sup>8</sup>

### Myotonic Dystrophy

Myotonic dystrophies are characterized by myotonia, the inability to relax muscles after sustained contraction. Myotonic dystrophy type 1 is an autosomal dominant, progressive myopathy presenting at any age and has increased severity in each successive generation.<sup>55</sup> Most patients present in the second to fourth decade with symmetrical bilateral ptosis, temporal wasting, meibomian gland dysfunction, Christmas tree cataracts, frontal alopecia, and distal limb weakness.<sup>50,55</sup> Abnormal RNA transcripts are toxic to muscle function.<sup>55</sup> Like CPEO, ptosis repair by frontalis sling is helpful early in the disease course. Facial weakness complicates ptosis repair both due to dryness and frontalis weakness limiting sling utility. Surgical ptosis repair may not be feasible in more advanced disease.

### Posttraumatic Ptosis

Levator muscle trauma can cause weakening. Trauma includes eyelid injuries and traction on the levator aponeurosis. Levator muscle injuries should be repaired.<sup>8</sup> Postoperative ptosis after modern anterior segment surgery is thought to be due to stretching of the levator aponeurosis.<sup>56</sup> Repetitive trauma from hard contact lens placement and wear is also associated with aponeurotic ptosis and Müller's muscle fibrosis.<sup>57,58</sup>

## CLINICAL EVALUATION AND PREOPERATIVE CONSIDERATIONS

During history taking and the physical examination, your goal is to discern three key pieces of information: type of ptosis, treatment plan, and factors that modify the treatment plan. For all patients, inquire about the onset and progression of ptosis, measure the *eyelid vital signs*, and take preoperative photographs.

### History and Examination

#### Adults

First determine whether the patient has common *acquired involutional ptosis*. Gradual progression makes it hard to determine the exact onset. Reviewing old photographs is helpful to document progression. Characteristics suggesting *unusual adult ptosis* include sudden onset, family history,

### BOX 12.4.2 Estimating the Amount of Resection for Simple Congenital Ptosis<sup>8</sup>

#### Levator Function Technique

##### Levator Function

2–3 mm (poor)  
4–5 mm (poor)  
6–7 mm (fair)  
8–9 mm (good)  
10–11 mm (good)

##### Intraoperative Lid Height

At upper limbus  
1–2 mm overlap  
2 mm overlap  
3–4 mm overlap  
5 mm overlap

#### MRD<sub>1</sub> Technique

##### Preoperative MRD<sub>1</sub>

3–4 mm (mild ptosis)  
2–3 mm (moderate ptosis)  
1–2 mm (marked ptosis)  
0–1 mm (severe ptosis)

##### Amount of Resection

10–13 mm  
14–17 mm  
18–22 mm  
>23 mm

diplopia, variable lid position, and associated facial movement problems.<sup>8</sup> Document the subjective effect of ptosis on the patient's vision. Visual field testing, with the eyelids relaxed and then taped open, documents vision improvement in the superior visual field.

#### Children

First determine whether the child has *simple congenital ptosis*. The ptosis will have been present since birth and does not progress. Assess for any characteristics of *unusual childhood ptosis*, including family history, developmental delay, or abnormal facies suggesting presence of a syndrome, extreme variation in ptosis throughout the day, and if the lid changes position with chewing or sucking.<sup>8</sup> Determine whether the child has associated ocular problems by measuring visual acuity and motility.

### Formulating a Treatment Plan

#### General Considerations

In all patients, ptosis repair surgery should be avoided if there is an increased risk for postoperative exposure keratopathy. Cautionary factors include poor tear film, corneal epitheliopathy, poor Bell's phenomenon, facial nerve weakness, or prior ptosis repair surgery. The ocular surface should be treated maximally before surgery. If vision is impaired, a limited lid lift can be performed.

The type of ptosis and *levator function* determine the best choice of surgery. Levator muscle shortening is used to correct ptosis with moderate to normal levator function. Ptosis responsive to phenylephrine eye drops can be corrected with a posterior approach Müller's muscle conjunctival resection.<sup>4,48,59</sup> Frontalis suspension procedures are used to correct ptosis with poor levator function and adequate frontalis function. Autologous fascia lata or silicone rod sling material can be used.<sup>60</sup>

The surgical incision should be located at the present or desired lid crease. For unilateral surgery, the lid crease should match the crease height of the nonoperative lid. For weak creases, the crease can be placed at the superior border of the tarsus.

Adults with dermatochalasis or brow ptosis may need additional procedures concurrent with ptosis repair surgery. Children with amblyopia need surgery performed sooner. Otherwise, surgery can be deferred until age 3–5, when more accurate levator function measurement is possible. For *simple congenital* ptosis with levator function of at least 3 mm, the amount of levator resection can be estimated based on levator function or preoperative MRD<sub>1</sub> (Box 12.4.2).<sup>8</sup>

Overall medical health of all patients should be assessed, and your surgical outcome expectations should match the patient or parental expectations.

### SURGICAL CORRECTION OF PTOSIS

#### Anesthesia

Ptosis repair is ideally performed under local anesthesia with light intravenous sedation. A minimal volume (1–1.5 mL per eyelid) of subcutaneous 2% lidocaine with 1:100 000 epinephrine and 0.75% bupivacaine provides adequate anesthesia for most patients. General anesthesia is used for young children and apprehensive adults.

Fig. 12.4.8 Key Steps in the Levator Aponeurosis Advancement Operation.

#### Levator Aponeurosis Advancement

**Patient preparation:** Mark the planned upper eyelid incision (Fig. 12.4.8A), give subcutaneous local anesthetic, and perform a full-face surgical wash.

**Skin incision and identification of the levator aponeurosis:** After making a skin incision at the marked crease, incise and dissect the orbicularis superiorly off the septum. Maintain hemostasis throughout. Open the septum

and dissect preaponeurotic fat from the underlying levator (Fig. 12.4.8B). *Dissection of the levator aponeurosis:* The levator is disinserted from anterior surface of the tarsus and separated from the underlying Müller's muscle by sharp and blunt dissection (Fig. 12.4.8C). *Levator aponeurosis advancement:* Place partial thickness 5–0 Prolene sutures in the central tarsus to attach the levator aponeurosis to the tarsus (Fig. 12.4.8D). *Intraoperative adjustments:* Sit the patient upright to assess lid height, contour, and symmetry between both sides, aiming for 1 mm of overcorrection. Adjust the suture position as necessary.

*Closure:* 6–0 Prolene is used in adults and 6–0 chromic suture is used in children. Reform the lid crease by attaching the skin or orbicularis to the underlying levator aponeurosis (Fig. 12.4.8E). The skin is closed with a running suture (Fig. 12.4.8F).

*Postoperative care:* Ice packs are used for 48 hours postoperatively to decrease bruising and swelling. Topical ophthalmic antibiotic ointment is placed on sutures and in the eyes for 1 week. Prolene sutures are removed 5–7 days after surgery.

## Frontalis Suspension

*Patient preparation:* Children are placed under general anesthesia. Mark the planned lid crease incision (Fig. 12.4.9A). Mark three 4-mm forehead incisions, including at the superior brow slightly medial to the medial limbus and slightly lateral to the lateral limbus and 1 cm above the brow in line with the pupil (Fig. 12.4.9A). For autologous fascia lata grafts, mark a line from the lateral femoral condyle to the anterior iliac crest. Administer local anesthetic and perform a full-face wash and leg wash if necessary. Autologous fascia lata will need to be harvested.<sup>61</sup>

*Skin incisions:* Use a 15 blade to make stab incisions down to the periosteum at the forehead marks (Fig. 12.4.9B). Make an incision at the marked lid crease (Fig. 12.4.9B). Identify the levator and expose the tarsus using the same technique as in the levator advancement surgery. Maintain hemostasis throughout the procedure with bipolar cautery. *Anchoring the implant:* Attach the sling to the tarsus with partial thickness 5–0 Mersilene sutures (Fig. 12.4.9C). *Suspending the lid:* Thread the sling onto a Wright needle. Pass each end of the sling through the skin crease incision, under the orbital septum, superficial to the orbital rim periosteum, and out the brow wounds. Next pass each end of the sling from the brow incision to the central forehead incision (Fig. 12.4.9C and D).

*Lid crease closure:* Form a lid crease by suturing the skin edges to the top of the tarsus with interrupted 7–0 Vicryl sutures, and close the skin with running 6–0 chromic suture (Fig. 12.4.9C and E). *Lid height adjustment:* Adjust tension on the sling ends, placing the lid margin at the limbus with appropriate contour. Join the ends of the sling with 5–0 Mersilene suture for fascia or a silicone Watzke sleeve for silicone rods (Fig. 12.4.9D). *Forehead closure:* Close the skin with 6–0 chromic suture (Fig. 12.4.9E).

*Postoperative care:* Topical ophthalmic antibiotic ointment is placed along the sutures and in the eyes for 1 week. Adults may use ice packs for 48 hours after surgery to decrease bruising and swelling.

## Complications

Careful surgical technique will minimize hemorrhage, infection, and vision loss. Patients should watch for the eyelids being swollen shut, increased pain, or vision loss and should be given an emergency number to call.

Careful intraoperative adjustments will provide the best possible symmetry of lid height, contour, and lid crease position between the two sides. Thorough preoperative evaluation and appropriate patient selection will minimize postoperative ocular surface problems.

### Undercorrection

Persistent ptosis is common with 10%–20% of patients being undercorrected.<sup>62</sup> Lid position should be re-evaluated 3–4 months postoperatively, allowing for adequate healing. Revision surgery is indicated if the ptosis remains visually significant.

### Overcorrection

Mild overcorrection can be improved by performing eyelid stretching exercises. Instruct the patient to close the eye, pull the eyelid down, and try to open the eye. Exposure keratitis can occur due to lagophthalmos, poor blink, or poor Bell's phenomenon. Medical treatments include frequent lubricating eyedrops during the daytime, nightly lubricating ophthalmic ointment, and punctal plug placement. Surgical correction is indicated for persistent overcorrection or keratitis.

Fig. 12.4.9 Key Steps the Frontalis Suspension Operation.

## Changes in Astigmatism

In general, children do not have significant changes in astigmatism up to 3 years after surgery but must be monitored closely for development of amblyopia.<sup>19,63</sup> Most adult patients have short-term changes in corneal astigmatism for up to 3 months after ptosis repair surgery.<sup>64,65</sup> At 1 year, remaining changes are not subjectively visually significant.<sup>66</sup> It is important to discuss a possible refractive change with patients preoperatively.

## OUTCOME

Rare progressive conditions, such as CPEO and muscular dystrophy, may require reoperation as disease progresses. Most patients with *common ptosis* have improved vision and stable eyelid position after ptosis repair surgery.

# Entropion

James W. Gigantelli

## 12.5

**Definition:** Entropion: a commonly encountered inward rotation of the tarsus and eyelid margin (Fig. 12.5.1).

### Key Features

- Symptoms and signs include ocular foreign body sensation, secondary blepharospasm, ocular discharge, epiphora, superficial keratopathy, and corneal scarring.
- Natural course is often progressive; early signs and symptoms may be intermittent.
- Numerous corrective techniques for this eyelid malposition are reported; many reflect the failure of earlier practitioners to appreciate this condition's pathophysiology.
- Multifactorial pathogenicity, including tarsotendinous instability, tarsoligamentous laxity, capsulopalpebral fascia dysfunction, preseptal orbicularis muscle override, axial position of the globe, and tarsoconjunctival foreshortening.
- Surgical goals are to normalize eyelid function and appearance by determining the active pathophysiological factors and addressing their direct surgical correction.

### INTRODUCTION

Early procedures to correct entropion can be categorized as vertically shortening the anterior lamella (skin and orbicularis muscle), vertically lengthening the posterior lamella (tarsus and conjunctiva), and/or controlling lamellar rotation. Procedures involving horizontal eyelid tightening were popularized by Fox, Bick, and others. Wies<sup>1a</sup> described a procedure utilizing full-thickness blepharotomy and eyelid margin rotation. Despite the

**Fig. 12.5.1 Right Lower Eyelid Entropion.** Note the inward rotation of the tarsal plate about the horizontal axis and resultant contact between the eyelid mucocutaneous junction and ocular surface. Multiple anatomical defects may be contributing to the eyelid presentation.

nonphysiological basis of this procedure, it gained wide acceptance due to its technical ease.

The mid-twentieth century heralded an anatomical approach to entropion repair. In 1963 DeRoeth<sup>1b</sup> and Jones et al.<sup>2</sup> separately identified the lower eyelid retractor system as pivotal in acquired entropion development. Jones et al.<sup>3</sup> also described surgical correction via lower eyelid retractor repair. Lower eyelid retractor microanatomy and physiology were further refined by Hawes and Dortzbach,<sup>4</sup> Goldberg et al.,<sup>5</sup> and others.<sup>6,7</sup> Orbicularis muscle functions in acquired and congenital entropion were clarified by Dagleish and Smith<sup>6</sup> and Tse et al.,<sup>8</sup> and tarsal plate and canthal ligament physiologies were advanced by Bengner and Musch,<sup>7</sup> Shore,<sup>9</sup> and Liu and Stasior.<sup>10</sup> Finally, the importance of tarsoconjunctival support in entropion was contributed by Shorr et al.<sup>11</sup> and Baylis and Hamako<sup>12</sup> and led to improved posterior lamellar substitutes and grafting techniques by Swamy<sup>13</sup> and others.<sup>14</sup>

### PREOPERATIVE EVALUATION AND DIAGNOSTIC APPROACH

A complete ocular history, including all prior eyelid procedures, and physical examination are essential. The general medical history and physical examination may be critical in uncovering systemic manifestations predisposing to entropion development.

### The Capsulopalpebral Fascia

Capsulopalpebral fascia dysfunction is central to the evaluation of congenital and acquired entropion (see Box 12.5.1 and Chapter 12.1). In cases in which the fascia clinically appears disinserted or dehiscenced from the inferior tarsus, histological observations disclose the capsulopalpebral fascia to sometimes be attenuated or only partially dehiscenced.<sup>15</sup> Clinical observations that identify lower lid retractor dysfunction include a higher eyelid resting position of the lid margin in primary gaze and an increased ability to passively distract the eyelid upward. Although some authors have stated that capsulopalpebral fascia dysfunction can result in a reduced vertical eyelid excursion, Bengner and Musch found normal lower lid excursion similar to the upper eyelid excursion observed in patients with aponeurogenic blepharoptosis.<sup>7</sup>

#### BOX 12.5.1 Preoperative Assessment of Entropion

##### Assessment of Capsulopalpebral Fascia Laxity

- Higher eyelid resting position in primary gaze
- Increased passive vertical eyelid distraction
- Increased depth of inferior conjunctival fornix
- Presence of a white infratarsal band

##### Assessment of Horizontal Eyelid Laxity

- Enhanced distraction of the eyelid from globe

##### Assessment of Relative Enophthalmos

- Exophthalmometry

##### Assessment of Preseptal Orbicularis Muscle Override

##### Assessment of Posterior Lamellar Support

- Vertical height of tarsal plate
- Presence of cicatrizing conjunctival disease

##### Assessment of Marked Orbital Fat Prolapse

In cases of retractor dysfunction, the fornix depth often increases. This can be measured against the contralateral fornix depth in unilateral entropion or against a normal inferior central fornix depth of 11 mm.<sup>16</sup> In some cases, a white band, representing the disinserted edge of the capsulopalpebral fascia, can be observed beneath the palpebral conjunctiva.

## The Tarsus and Canthal Ligament

Some studies suggest that age-related horizontal lower lid laxity occurs especially in patients who have chronic entropion. Histopathological studies of eyelids manifesting entropion demonstrated collagen degradation and loss of elastic fibers affecting multiple eyelid tissues including the tarsus.<sup>17,18</sup> This laxity often results from stretching of the lateral canthal ligament.

## Enophthalmos

Another determinant of the appositional pressure between globe and eyelid is the relative position of the globe. Bick demonstrated that entropion could be temporarily corrected by the intraconal injection of 2–4 mL of saline. Several studies have demonstrated reduced axial globe length as a factor predisposing to the development of involutional entropion.<sup>19,20</sup>

## Orbicularis Muscle

Several investigators have demonstrated a superior migration of the preseptal orbicularis subunit toward inferior tarsal margin.<sup>6,21</sup> It is unclear whether this muscular bunching is a primary phenomenon or an epiblepharon. Clinical evaluation for preseptal orbicularis override is subjective and should be carried out with the eye in primary gaze position, after a spontaneous blink, and following forceful eyelid closure.

## The Posterior Lamella

Entropion can be precipitated by the reduction of tarsoconjunctival vertical height. This can occur in either the presence (cicatricial entropion) or absence of cicatrizing conjunctival disease. Age-related decrease in the vertical dimension of the tarsal plate and a reduced tarsal height associated with involutional entropion have been documented.<sup>6,22</sup>

The majority of cicatricial entropion cases involve trachoma, Stevens–Johnson syndrome, ocular cicatricial pemphigoid, chronic meibomian gland inflammation, chemical and radiation injury, or postoperative fibrosis. Additional diagnostic considerations include sarcoidosis, atopic keratoconjunctivitis, ocular rosacea, toxic epidermal necrolysis, membranous conjunctivitis, herpes zoster ophthalmicus, progressive systemic sclerosis, dysthyroidism, graft versus host disease, prostaglandin associated orbitopathy, and neoplasm. Patients with progressive processes require preoperative and perioperative immunomodulation to suppress their disease activity.<sup>23,24</sup> When the primary process is uncertain, a diagnostic evaluation, including possible conjunctival biopsy, is indicated. Kemp and Collin<sup>25</sup> offered a grading system for cicatricial change. This system focuses on the position of the meibomian gland orifices, conjunctivalization of the eyelid margin, the position and orientation of the cilia, assessment of tarsal plate structure, keratinization of the palpebral conjunctiva, assessment of posterior lamellar scarring, and symblepharon formation.

## Other Factors

Profoundly prolapsing orbital fat has been suggested as a risk factor for lower eyelid entropion. Bartley et al.<sup>26</sup> reported entropion in pediatric patients manifesting morbid obesity or facial dysmorphism. Carter et al.<sup>27</sup> reported excessive lower eyelid fat prolapse associated with entropion in Asian patients.

## DIFFERENTIAL DIAGNOSIS

Epiblepharon, distichiasis, trichiasis, and eyelid retraction may be confused with entropion. These clinical entities arise from different pathophysiologies, follow a different clinical course, and necessitate different therapies.

## Epiblepharon

In epiblepharon, a horizontal fold of redundant pretarsal skin and orbicularis muscle extends beyond the eyelid margin and compresses the eyelashes against the globe (Fig. 12.5.2). The condition is usually bilateral,

**Fig. 12.5.2 Epiblepharon.** Note the bilaterality, loss of the lower eyelid skin crease, and overriding skin fold. Normal rotational orientation of the tarsal plate distinguishes this condition from entropion.

observed shortly after birth, commonly involves the lower lid, and may be exacerbated in downgaze. Although both epiblepharon and congenital entropion result from lower eyelid retractor defects, their clinical presentation and course contrast sharply.<sup>28</sup> Nearly 80% of children experiencing epiblepharon have no ocular complaints.<sup>29</sup> The condition frequently resolves with normal facial growth. Treatment is reserved for symptomatic cases. Reformation of the lower eyelid crease through the removal of a horizontal skin–orbicularis muscle ellipse with suture fixation to the anterior surface of the capsulopalpebral during wound closure is curative.<sup>28,30</sup>

## Trichiasis

Trichiasis is an acquired condition in which cilia arise from their normal anterior lamellar position but are misdirected toward the ocular surface. This usually results from inflammation-induced scarring of the eyelash follicles. Treatment is usually based on the number, distribution, and severity of the misdirected cilia. Treatment modalities include mechanical epilation, electrolysis, radiofrequency ablation, laser photoablation, cryotherapy to the posterior eyelid lamella, anterior eyelid lamellar recession, and surgical excision of the eyelash bulbs.

## Congenital Entropion

True congenital lower eyelid entropion is rare, and its hypothesized pathophysiology is derived mostly from intraoperative observation.<sup>26,28,30</sup> Congenital lower eyelid entropion is believed to occur when both the anterior and posterior attachments of the capsulopalpebral fascia are dysfunctional. This accounts for the poorly formed lower lid skin crease in addition to the inward tarsal rotation in affected children. Unlike epiblepharon, congenital entropion does not resolve spontaneously and requires prompt surgical intervention.

The horizontal tarsal kink syndrome is a rare form of congenital upper eyelid entropion. In this condition, a right-angled inward rotation of the tarsal margin causes constant apposition of the eyelid margin to the ocular surface and results in early, severe corneal complications. The cause of this variant remains unknown. The potential for severe corneal complications requires early recognition and prompt therapy. Surgical interventions include tarsal eversion sutures, transverse blepharotomy, and resection of the tarsal kink with eversion sutures.<sup>31</sup>

## ALTERNATIVES TO SURGERY

Patients who have entropion should be evaluated as possible surgical candidates. The extent of ocular findings, patient's age, and systemic comorbidities must be considered when devising a treatment plan. Medical therapy is appropriate before surgical intervention and for patients who refuse or are too ill to undergo surgery. Symptoms may be ameliorated through the use of artificial tears, lubricating ointments, or a bandage soft contact lens. Temporary eyelid eversion can sometimes be obtained by repositioning the anterior lamella away from the eyelid margin with tape.

## Quickert–Rathbun Sutures

Eyelid margin rotation and lamellar migration can be corrected with placement of several well-spaced and tightly tied full-thickness sutures.<sup>32</sup> Chromic gut, nylon, and silk sutures create equivalent scarring, but silk and nylon sutures incite epithelial ingrowth along the suture tract.<sup>33</sup> Consensus is that entropion repair by everting sutures lacks permanence with

recurrence rates nearing 50% by 2 years.<sup>32,34</sup> This shortcoming may nevertheless be acceptable in patients who are poor surgical risks or for whom a temporary repair is adequate.

## Botulinum Toxin

Office-based subcutaneous or intramuscular injection of the nasal and temporal lower eyelid with botulinum toxin may provide temporary entropion correction.<sup>35</sup> Chemodenervation is noted within 3–5 days of administration and may last up to 6 months. Injections in the medial lower eyelid may be complicated by temporary medial ectropion, punctal eversion, or inferior oblique muscle paresis.

## ANESTHESIA

Entropion surgery is an outpatient procedure usually performed under local anesthesia. Monitored anesthesia care, which combines intravenous sedation with local analgesia, may be performed instead. Pediatric patients usually require general anesthesia.

A 1:1 dilution of lidocaine (lignocaine) 2% with 1:100 000 epinephrine (adrenaline) and bupivacaine 0.75% combined with hyaluronidase (150 units per 10 mL of injectable anesthetic) provides excellent anesthesia. Hyaluronidase enhances diffusion of the anesthetic solution, thereby reducing tissue distortion and preserving intraoperative tissue anatomy. When coadministered with epinephrine, it does not reduce the anesthetic duration of action.

Sodium bicarbonate (1 mL of 1 mEq/mL [1 mmol/mL] solution per 10 mL of injectable anesthetic) may also be added to local anesthetic solutions to decrease pain on injection.<sup>36</sup> Tissue infiltration or a regional nerve block is best performed with a 27- or 30-gauge hypodermic needle. Epinephrine-induced vasoconstriction requires up to 10 minutes, so tissue infiltration should be performed before the surgical skin preparation and patient draping.

## GENERAL TECHNIQUE

The advances and improved surgical success in entropion management occurred through the appreciation of its pathophysiological and anatomical basis.<sup>37</sup> The surgical procedure as planned entails the correction of each underlying defect. Frequently entropion is multifactorial in origin and requires the correction of a combination of defects. Several authors have demonstrated that a single entropion procedure performed universally provides insufficient short- and long-term results.<sup>38,39</sup> In broad terms, entropion surgery may include:

- Correction of capsulopalpebral fascia dysfunction.
- Reduction of horizontal lower eyelid laxity.
- Debulking of excessive lower lid fat.
- Prevention of preseptal orbicularis muscle shifting.
- Reconstruction of vertically foreshortened eyelid posterior lamellar tissue.

In cases of capsulopalpebral fascia dysfunction, the fascia must be vertically advanced or reattached to the inferior border of tarsus. Transcutaneous and transconjunctival approaches are described for this repair.<sup>38,40</sup> Both approaches can be combined with techniques to correct horizontal laxity, prolapsed orbital fat, and preseptal orbicularis muscle override. The transconjunctival approach readily lends itself to the synchronous placement of a posterior lamellar graft. Except in cases where posterior lamellar foreshortening exists as a causative factor, the surgical management of entropion whether by transcutaneous or transconjunctival approach has a success rate of 97% or greater.<sup>40–43</sup>

The capsulopalpebral fascia can be advanced to the inferior tarsal border with or without its separation from the orbital septum. Separation of the septum from the fascia allows broader fascial exposure and a reduced likelihood of entrapping orbital septum during the advancement.

Surgical correction of horizontal eyelid laxity addresses foreshortening by either resection of the tarsal plate or plication-resection of the lateral canthal ligament. Greater dysfunction appears to reside in the canthal ligament and its attachments rather than in the tarsal plate itself.<sup>9</sup> Reconstruction of the lateral canthal ligament is therefore preferred over purely tarsal resections performed in the central eyelid. This removes the dysfunctional canthal ligament and preserves the integrity of the relatively healthier tarsus. Orbicularis muscle dysfunction is corrected by creation of a fibrous barrier between the orbicularis muscle and deeper eyelid structures at the junction of the muscle's pretarsal and preseptal subunits. This can be

achieved through a cutaneous incision placed at this level, the stimulation of fibrosis through the use of sutures, or the extirpation of a preseptal muscular subunit.<sup>38</sup>

Progressive inflammatory processes such as ocular cicatricial pemphigoid, scleroderma, and sarcoidosis are likely to require local and/or systemic immunomodulators to stabilize the disease course before surgical intervention.<sup>24,44</sup> For certain disease states, manipulation of the eyelid posterior lamella may precipitate a local inflammatory exacerbation.<sup>45</sup> In such situations, deviation from direct correction of the pathophysiological defect may be appropriate. A modest advance of the capsulopalpebral fascia may suffice to correct mild to moderate "cicatricial" entropion and obviate the need for potentially dangerous surgical manipulation of the tarsus and conjunctiva.<sup>44</sup>

In most cases of tarsoconjunctival foreshortening, once the process is identified and optimal immunosuppression achieved, a posterior lamellar technique is performed. This may take the form of a tarsal out-fracture with marginal rotation or placement of a posterior lamellar graft. The transverse tarsotomy directly addresses those eyelid structures affected by the underlying disease process.<sup>46,47</sup> When manipulation of these layers is limited, the risks of avascular necrosis of the lid, cutaneous scarring, and levator aponeurosis damage are minimized.

The selection of an appropriate donor material is essential when posterior lamellar support is needed. Favored tissue should be autologous, epithelium covered, and semirigid. Materials utilized for tarsoconjunctival reconstruction or replacement have included tarsoconjunctival flaps and grafts, hard palate mucosa, nasal chondromucosa, and nasal mucoperiosteum. Although an autologous tarsoconjunctival composite flap or graft provides the most exact reconstruction, these tissues may be in short supply, especially if the primary disease process is either advanced or bilateral. The hard palate mucosa and nasal mucoperiosteum are the current alternative tissues of choice.<sup>14</sup> They are plentiful, easy to harvest, minimally resorptive, structurally similar to tarsus, and can be harvested repeatedly if necessary. Other materials that may be grafted to lengthen the tarsus include amniotic membrane, periosteum, temporalis fascia, banked sclera, irradiated homologous aorta, porous polyethylene, and polytef.<sup>11,12,48–51</sup>

## SPECIFIC TECHNIQUES

### Retractor Reattachment

In most cases of involutional entropion, retractor plication or reattachment effectively corrects the defect.<sup>52</sup> In patients without posterior lamellar foreshortening, a transcutaneous approach is appropriate. A 4–0 silk traction suture is passed horizontally through the central lower eyelid margin and clamped to the drape overlying the brow (Fig. 12.5.3). A cutaneous incision is made 4 mm inferior to the eyelid margin (or 2.5 mm inferior to the lower lid lashes). This extends from immediately lateral to the lacrimal punctum to beyond the lateral canthal angle. The orbicularis muscle is buttonholed at the junction of the pretarsal and preseptal subunits (see Chapter 12.1) and separated for the full length of the skin incision (Fig. 12.5.4). A myocutaneous flap is developed from the incision to the inferior orbital rim.

**Fig. 12.5.3** A Subciliary Incision Has Been Made Following the Placement of an Intramarginal 4–0 Silk Traction Suture.

**Fig. 12.5.4** Westcott Scissors Divide the Pretarsal and Preseptal Subunits of the Orbicularis Muscle.

**Fig. 12.5.5** Following Opening of the Orbital Septum, the Lower Eyelid Fat Is Retracted Inferiorly. The capsulopalpebral fascia (open arrow) appears disinserted from the inferior tarsus (closed arrow).

The “free edge” of the capsulopalpebral fascia is often visualized several millimeters inferior to the tarsal border. The orbital septum can be buttonholed 1 mm inferior to its fusion with the capsulopalpebral fascia and opened the horizontal length of the anterior lamellar incision. An important surgical landmark is the lower eyelid fat, which rests between the septum and fascia. The three lower lid fat pads may be dissected from the anterior surface of the capsulopalpebral fascia (Fig. 12.5.5). If necessary, profoundly prolapsed fat may be debulked.

The capsulopalpebral fascia is then advanced upward and reattached to the inferior tarsal border (Figs. 12.5.6–12.5.8). Fascial identification can be confirmed by grasping the tissue in toothed forceps and having the patient gaze inferiorly. When gross disinsertion is present, the fascia is advanced to the inferior tarsal border. In cases in which the fascia is attenuated but not disinserted, the fascia is surgically disinserted by the surgeon, a narrow horizontal strip excised, and the remaining fascia reattached to the inferior tarsal border. Reattachment to the tarsus is performed with several interrupted 6-0 Prolene sutures.<sup>53</sup>

In patients demonstrating preseptal orbicularis muscle override, a 5–8 mm vertically wide horizontal strip of preseptal muscle is extirpated en bloc from the muscle's posterior surface (Fig. 12.5.9). The skin incision can be closed with a running 6-0 mild chromic or nylon suture. Topical antibiotic ointment is sufficient for postoperative infection prophylaxis.

### Lateral Tarsal Strip Procedure

A horizontal tightening of the lower lid may be combined with reattachment of the retractors or be done as a separate procedure (see Chapter

**Fig. 12.5.6** The Free Edge of the Capsulopalpebral Fascia Can Be Elevated Easily From the Underlying Conjunctiva. Vertical fascial advancement and reattachment to tarsus is performed following resuspension of the lateral tarsal strip.

**Fig. 12.5.7** The Capsulopalpebral Fascia Is Advanced and Sutured to the Inferior Border of the Tarsal Plate. Care must be taken to obtain a solid purchase of the inferior tarsus and to avoid advancing the fascia superiorly along the tarsal anterior surface.

**Fig. 12.5.8** The Completed Lower Eyelid Retractor Advancement. Multiple point fixation with nonabsorbable suture ensures permanence.

12.6).<sup>54</sup> The tightening is best performed using a standard lateral tarsal strip technique.<sup>55</sup> A lateral canthotomy and inferior cantholysis of the canthal ligament are performed. Within the temporal eyelid, the anterior and posterior lamellae are separated from one another beginning at the gray line and extending across the anterior surface of the tarsus. The lid margin is then de-epithelized. The palpebral conjunctiva is disinserted from the inferior tarsal border to complete formation of the tarsal strip. The redundant tissues of the strip are determined by drawing the strip to the lateral orbital tubercle. The excess tissue is excised and the new lateral

**Fig. 12.5.9** A Strip of Preseptal Orbicularis Muscle Is Extirpated Using Westcott Scissors. Muscle manipulation predisposes to hemorrhage; complete hemostasis are essential.

border of tarsus is resuspended to periosteum at the lateral orbital tubercle with either two interrupted or a single horizontal mattress 4-0 gauge suture. Use of a small-radius, half-circle (P-2, S-2, or D-2) needle facilitates the periosteal anchor at the lateral orbital tubercle.

Meticulous hemostasis is established before closure. An absorbable 6-0 horizontal mattress canthopexy suture creates an acute canthal angulation and prevents imbrication of the upper lid over the temporal lower lid. To enhance esthetics, a small cutaneous triangle may be excised from the inferior wound margin lateral to the canthal angle. The lateral canthotomy is closed in a layered fashion. In some cases, Quickert-type lid sutures may enhance the marginal rotation.<sup>56-59</sup>

## Transverse Tarsotomy

In moderate cicatricial entropion, a posterior transverse tarsotomy with eyelid margin rotation provides excellent correction. A 4-0 silk traction suture is placed horizontally through the central eyelid margin and the lid everted over a Desmarres retractor. A transverse incision is created through the palpebral conjunctiva and tarsus using a scalpel. The tarsotomy should be made equal to or greater than 3 mm from the eyelid margin to avoid the marginal vascular arcade (Fig. 12.5.10). The marginal rotation is accomplished using double-armed 6-0 sutures at multiple sites along the eyelid. The suture is first passed in a horizontal mattress fashion through the anterior edge of the nonmarginal tarsal plate. Each arm of the suture is then passed through the tissues of the marginal strip between the planes of the tarsus and orbicularis muscle exiting the skin immediately anterior to the cilia. Sutures are then tied under appropriate tension to evert the margin. Prophylactic topical antibiotic ointment for 1 week is sufficient.

## Hard Palate Mucosal Graft

In severe cicatricial entropion, the posterior eyelid lamella often requires buttressing. After the nonmarginal tarsal plate is everted over a Desmarres retractor and the transverse tarsotomy is performed, a limited dissection is performed in the marginal strip between the planes of the tarsus and orbicularis muscle.

A hard palate graft may be harvested using a local anesthetic block of the greater palatine and nasopalatine nerves followed by diffuse submucosal infiltration. The mucosa is outlined with a marking pen and the palate incised with a scalpel. The graft is undermined with the scalpel or a sharp periosteal elevator. Avoiding the greater palatine foramen and palatine vessels minimizes bleeding. The palatal defect is not closed but may be covered with an acrylic retainer or the patient's upper dentures, if available.

The graft is thinned of fatty tissue on its submucosal surface and secured in the posterior eyelid lamellar defect with 6-0 absorbable sutures along its nonmarginal and lateral borders (Fig. 12.5.11). The rotated marginal strip of the eyelid is then secured to the anterior surface of the graft with three double-armed sutures, as previously described for the transverse tarsotomy procedure. A Frost traction suture and pressure dressing are used for 5-7 days to immobilize the lid in a stretched position. Oral

## TRANSVERSE TARSTOMY OF POSTERIOR LAMELLA

**Fig. 12.5.10** The Transverse Tarsotomy of the Posterior Lamella Allows Rotation of the Marginal Eyelid Segment. Incision placement preserves the integrity of the marginal vascular arcade.

## BUTTRESSING THE POSTERIOR LAMELLA

**Fig. 12.5.11** Posterior Lamella Buttressing Is Accomplished Through a Hard Palate Graft. Graft bed preparation and marginal segment rotation are performed similarly as for posterior tarsotomy.

antibiotics are prescribed until removal of the dressing, after which topical antibiotic ointment is administered.

When hard palate grafts are placed in the upper lid, corneal protection by copious surface lubrication or a bandage contact lens is frequently necessary.

## COMPLICATIONS

Postoperative complications can be reduced through meticulous preoperative planning and intraoperative technique. The best way to prevent recurrent entropion is through the appropriate selection of surgical procedures. When entropion recurs during the early postoperative period, the patient should be re-evaluated for overlooked or undercorrected predisposing factors. Later recurrences may be due to progression of underlying pathophysiology. Recurrences in patients with cicatrizing conjunctival disease may be due to graft failure, graft contracture, or disease progression.

### Overcorrection

Overcorrection of the eyelid margin position may follow excessive advancement of the capsulopalpebral fascia, attachment of the fascia too high on the anterior tarsal surface, undercorrected horizontal eyelid laxity, and incorporation of the orbital septum in the advancement or surgical closure. Postoperative ectropion can also occur following unintended extirpation of the pretarsal orbicularis subunit or excessive vertical skin resection. If the ectropion is mild and tolerated by the patient, conservative management with time, warm compresses, and massage may suffice. When it is severe, transposition of a preseptal orbicularis strip closer to the eyelid margin or full-thickness skin grafting may be necessary.

### Hematoma

The risk of hematoma can be reduced by preoperative discontinuation of medications that impair platelet function and the clotting cascade. Meticulous hemostasis through intraoperative use of electrocautery is essential. Attention should be given to the lateral branches of the palpebral arcades following lateral cantholysis and to areas of extirpation of the preseptal orbicularis muscle. When eyelid hematomas occur, they are usually self-limiting and resolve with periodic warm compresses and observation.

Hemorrhage that occurs at a hard palate donor site usually originates from the greater palatine or nasopalatine artery. It can be controlled with digital pressure, submucosal epinephrine injection, conservative electrocautery, chemical cautery, cellulose or collagen sponge, periodontal putty, or a palatal stent.<sup>60</sup>

### Eyelid Retraction

Postoperative eyelid retraction usually results from excessive horizontal tightening of the tarsus or excessive vertical advancement of the capsulopalpebral fascia. It is also important that the lateral tarsal strip is reattached to Whitnall's lateral orbital tubercle rather than the lateral raphe of the orbicularis complex. An excessively shortened tarsal strip can be resuspended from either the superior crus of the lateral canthal ligament or a periosteal strip elevated from the lateral orbital wall.

### Exposure Keratopathy

Corneal epithelial damage can develop from postoperative lagophthalmos, exposed conjunctival sutures, lagophthalmos, and keratinized hard palate

grafts. This risk is higher following upper lid entropion repair. Postoperative lagophthalmos can result from excessive capsulopalpebral advancement, orbicularis extirpation, or skin excision. Treatment includes ocular surface lubricants, bandage soft contact lens, suture removal, or dermabrasion of the keratinized graft.

### Ptosis

Aponeurogenic ptosis can complicate the repair of cicatricial upper lid entropion. The posterior fibers of the levator aponeurosis attach to the inferior one-third of the tarsal plate's anterior surface. During posterior tarsotomy, it is important to avoid disrupting these fibers.

## OUTCOME

Advances in the understanding of entropion have provided surgeons with improved, more reproducible, and longer-lasting treatment options. A systematic approach to the evaluation and treatment of this condition ensures that patients will benefit from these therapeutic outcomes. Appropriate surgical procedure selection should result in the immediate correction of the eyelid malposition. Most patients report symptomatic relief as early as their first postoperative day. Except in cases of posterior lamellar foreshortening, surgical management of entropion has a success rate of 97% or greater.<sup>40</sup> When tarsoconjunctival contraction is present, surgical success still exceeds 90%. An exception occurs in ocular cicatricial pemphigoid, where lower success is predicted.<sup>25,46</sup>

# Ectropion

*Robi N. Maamari, Steven M. Couch*

# 12.6

**Definition:** Ectropion is an outward rotation of the eyelid margin from the eye.

## Key Features

- Ectropion may result from progressive age-related eyelid laxity, vertical skin shortening, orbicularis muscle weakness, or mechanical force on the eyelid.
- Lower eyelid ectropion result in epiphora, palpebral and conjunctival surface irritation and keratinization, and corneal exposure with potential corneal ulceration and scarring.
- Surgical correction aims to re-establish proper eyelid margin apposition against the ocular surface.

## Associated Features

- Epiphora.
- Conjunctival erythema.
- Exposure keratopathy.
- Ocular surface pain.

## INTRODUCTION

Ectropion is an outward rotational displacement of the eyelid margin that is frequently encountered in clinical practice. This eyelid malposition most commonly affects the lower eyelid but can also occur in the upper eyelid. Clinically, it is important to identify the etiology of ectropion to properly select a surgical intervention that addresses the underlying anatomical defect.

## PREOPERATIVE EVALUATION AND DIAGNOSTIC APPROACH

A thorough ocular history should be taken before physical examination. The surgeon should specifically ask about a history of facial palsy, previous periocular surgery, and prior facial trauma. Common symptoms reported by patients with ectropion include eye irritation and redness caused by ocular surface exposure and tearing due to punctal malposition or laxity-induced lacrimal pump dysfunction. With long-standing ectropion, the exposed palpebral conjunctiva may become keratinized, leading to symptoms of chronic redness, discharge, and bleeding.

When performing the ophthalmic examination, it is important to carefully assess eyelid laxity, eyelid margin appearance, medial and lateral canthal integrity, orbicularis muscle tone, anterior and posterior lamellar characteristics, and lower eyelid retractor anatomy (Box 12.6.1).

## Eyelid Laxity Evaluation

The lower eyelid naturally apposes the globe when the eye is open and throughout the entire blinking cycle. When pulled downward and released, a normal eyelid quickly recoils back to its normal position against the globe. In the presence of diminished tone or excessive laxity, the eyelid recoils slowly or requires the eye to blink one or more times to return to position. If needed, a measurement of laxity can be taken between the ocular surface and the downward pulled eyelid (lower eyelid distraction

test). Normally, the eyelid cannot be distracted more than 6 mm from the ocular surface (Fig. 12.6.1).

## Medial Canthal Tendon Laxity

Lateral traction is applied to the lower eyelid and the total amount of inferior punctal displacement is measured. A shift in inferior punctal position by more than 1–2 mm with traction indicates medial canthal laxity. Rarely, patients with marked dehiscence may require tendon repair, a procedure that is difficult because of the lacrimal drainage system.

## Lateral Canthal Tendon Laxity

The normal lateral canthal angle maintains an acute confluence that is positioned 1–2 mm medial to the lateral orbital rim. Laxity is present when

### BOX 12.6.1 Preoperative Evaluation of Ectropion

Full ocular history

General ocular examination

Examination of specific eyelid changes

- Eyelid laxity
  - Horizontal eyelid laxity
  - Medial canthal tendon laxity
  - Lateral canthal tendon laxity
- Lacrimal puncta evaluation
- Anterior lamellae inspection
- Orbicularis muscle tone
- Eyelid masses
- Inferior eyelid retractor laxity

**Fig. 12.6.1 Lower Eyelid Distraction Test: The Lower Eyelid Is Pulled From the Globe and the Distance Between the Eyelid Margin and the Globe Can Be Measured.** This is an example of severe lower eyelid laxity.

the lateral canthus demonstrates medial displacement, rounding of the angle, or thinning of the canthal skin. Additionally, laxity is confirmed when medial eyelid traction displaces the canthus nasally by more than 1–2 mm.

### Lacrimal Puncta Evaluation

In the normal eyelid, puncta are not visible on passive external evaluation. Visualization of the puncta before eyelid distraction suggests medial eyelid ectropion. Chronic ectropion with punctal malposition can result in punctal stenosis or obliteration secondary to scarring.

### Anterior Lamellae Inspection

Vertical shortening of the lower eyelid anterior lamella with eversion of the eyelid margin can result from actinic skin damage, facial trauma, chronic eyelid malposition (involutional or paralytic), and prior surgical procedures including blepharoplasty. In mild cases, vertical tension lines in the eyelid skin can be visualized and manual elevation of the cheek skin improves the ectropion by diminishing the downward tension. Limitation of superior migration of the eyelid margin in upgaze and eversion of the margin when opening the mouth widely also indicate a shortage of skin in the anterior lamella.

### Orbicularis Oculi Muscle Tone

The resting orbicularis muscle tone allows the lower eyelid to remain well apposed to the ocular surface. Adequate muscle tone is also required for proper lacrimal pump function. Orbicularis muscle weakness is assessed during forced eyelid closure. Lagophthalmos results from the exaggerated horizontal eyelid laxity caused by orbicularis weakness. Additional signs of facial nerve palsy, including brow ptosis, diminished forehead rhytids, reduced nasolabial folds, and smile asymmetry should be evaluated.

### Eyelid Masses

Eyelid masses, such as neoplasms or cysts, can physically displace the lower eyelid margin as a result of both mass effect and the gravitational force on the mass shifting the eyelid margin down and away from the globe (Fig. 12.6.2). It is important to thoroughly inspect the conjunctival surfaces and fornices in addition to a careful examination of the anterior lamellar tissue for any cicatricial changes caused by local neoplastic infiltration.

### Lower Eyelid Retractor Dehiscence

Inspection of the posterior lower eyelids allows visualization of the relationship between the tarsal plate and the lower eyelid retractors. Laxity of the eyelid retractors may be associated with ectropion, especially in the

setting of severe horizontal laxity. Profound retractor attenuation may lead to excessive conjunctival redundancy and poor definition of the inferior fornix.

## DIFFERENTIAL DIAGNOSIS

### Involutional Ectropion

Involutional changes are the most common cause of ectropion and result from age-related laxity in the supporting structures of the lower eyelid (Fig. 12.6.3). It typically progresses from the medial eyelid and extends laterally based on the degree of lower eyelid retractor dehiscence and horizontal laxity. Initially, patients may only report epiphora due to the lower punctal eversion caused by early medial ectropion. Additional contributing structural changes include elongation of the tarsus, inferior displacement of the pretarsal orbicularis, and increased laxity of the medial and lateral canthal tendons.<sup>1</sup> As a result of the horizontal laxity and diminished pretarsal orbicularis support on the tarsal plate, preseptal orbicularis contraction predominantly acts on the inferior tarsal margin, exacerbating the eyelid eversion.<sup>2</sup> With progression, ocular exposure results in conjunctival inflammation and late-stage keratinization, tarsal thinning, eyelid margin thickening, and lagophthalmos—all of which contribute to worsening of the ectropion.

### Cicatricial Ectropion

Cicatricial ectropion is caused by scarring or vertical shortening of the lower eyelid anterior lamella due to previous trauma, eyelid and facial surgery, or a variety of actinic or infiltrative conditions (Fig. 12.6.4). Occasionally, acute entities causing cicatricial changes such as allergic blepharitis can be reversed with discontinuation of the offending agent or treatment with topical corticosteroids (Fig. 12.6.5). Cutaneous fibrosis and infiltration can be seen with skin malignancies and a wide variety of cicatrizing dermatological conditions. Suspicious lesions should be biopsied before eyelid surgery. Epidermal contraction can also be observed following long-standing involutional or even paralytic ectropion.

### Paralytic Ectropion

Paralytic ectropion is caused by decreased tone and weakened contraction of the orbicularis muscle due to facial nerve palsy (Fig. 12.6.6). The underlying facial palsy can result from Bell's palsy, surgical or traumatic injury, and stroke. Patients with pre-existing horizontal laxity before the facial nerve palsy may develop significant ectropion and lagophthalmos. Epiphora is commonly present due to reflex tearing from exposure keratopathy, punctal eversion, and an ineffective lacrimal pump mechanism due to improper orbicularis contraction. If the palsy is transient and recovery is

**Fig. 12.6.4** Cicatricial Ectropion From Severe Actinic Damage to the Lower Eyelid Skin and Previous Skin Cancer Resection.

**Fig. 12.6.5** Bilateral Cicatricial Ectropion Caused by Severe Allergic Blepharitis.

**Fig. 12.6.6** Paralytic Ectropion Associated With Seventh Nerve Palsy.

expected (i.e., Bell's palsy), use of lubricating ointment is sufficient until the palsy resolves. Surgery is typically required to correct ectropion caused by a permanent facial palsy.

## Mechanical Ectropion

Mechanical ectropion is observed when a mass causes the eyelid margin to shift away from the globe (see Fig. 12.6.2). This can be caused by a tumor or cyst near the eyelid margin pulling the eyelid down and away. Alternatively, periocular edema, conjunctival chemosis, and conjunctival growths and cysts can mechanically push the eyelid margin away from the globe. Treatment should initially address the underlying cause with medical intervention or resection of the causative mass. Although coexisting

involutional or cicatricial ectropion often is present, surgical intervention should be performed only if residual ectropion persists after treatment of the primary mechanical cause.

## Congenital Ectropion

Congenital ectropion is rare but commonly observed with absence or atrophy of the tarsal plate, conjunctival edema after birth trauma, and eyelid malformations with skin shortage and retraction. It is most often seen in association with Down syndrome but can also be associated with the blepharophimosis syndrome. If corneal exposure is mild or expected to resolve, as seen in cases with conjunctival chemosis from birth trauma, treatment with topical lubricants may be adequate. In more severe cases, skin grafting may be required to address the skin shortage and prevent corneal scarring and amblyopia.

## ALTERNATIVES TO SURGERY

Patients with symptomatic ectropion must be evaluated for surgical intervention to prevent corneal decompensation that can progress to ulceration and scarring from exposure. Medical treatment with artificial tears and ointment may be attempted before surgical intervention in patients with mild symptoms and in patients with systemic comorbidities preventing them from undergoing the surgical procedure.

## ANESTHESIA

Surgical repair of ectropion is an outpatient procedure that can be performed using only local infiltrative anesthetic in the physician's office or minor procedure room. A 1:1 solution of 2% lidocaine with 1:100 000 epinephrine and 0.75% bupivacaine provides satisfactory local analgesia. A subcutaneous injection of local anesthetic is often adequate for procedures involving the anterior lamella, but a transconjunctival injection may be required in surgeries involving posterior lamellar structures.

Monitored anesthesia care combines local anesthesia with intravenous sedation with propofol and should always be considered when skin harvesting and grafting is being performed. Finally, general anesthesia should be utilized for all pediatric patients and apprehensive adults.

## GENERAL TECHNIQUES

Numerous techniques have been described to correct ectropion. Early procedures include a lateral canthal shortening procedure described in 1812 by Sir William Adams,<sup>3</sup> an eyelid wedge excision procedure performed by Von Ammon in 1831,<sup>4</sup> and several variations of the traditional Kuhnt-Symanowski procedure.<sup>5,6,7</sup> Modern surgical procedures utilize our increased understanding of eyelid anatomy and physiology to address the specific underlying structural mechanism causing ectropion.

Thorough preoperative evaluation is critical to determine the proper surgical intervention based on presence of horizontal eyelid laxity, vertical redundancy and laxity, anterior lamellar shortening, or a combination of these conditions. When ectropion is caused by horizontal laxity, eyelid shortening is the treatment of choice. Presence of vertical eyelid laxity and conjunctival redundancy requires reattachment of the lower eyelid retractors. When anterior lamellar shortening due to cicatricial changes exist, surgical treatment is guided by the location and degree of cicatricial ectropion. In mild cases of cicatricial ectropion, horizontal tightening of the eyelid may be sufficient. Cases exhibiting more severe cicatricial findings may require skin grafts and skin flaps to adequately lengthen the anterior lamella. Importantly, patients may exhibit ectropion secondary to more than one cause and may require multiple procedures to fully address the condition.

## SPECIFIC TECHNIQUES

### Involutional Ectropion

#### Lateral Tarsal Strip Procedure

In 1969, Tenzel described the lateral canthal sling procedure for treatment of lagophthalmos and lower eyelid elasticity, in which the lower arm of the canthal tendon is passed through a buttonhole created in the upper canthal tendon and attached to the temporal periosteum.<sup>8</sup> Subsequently in 1979, Anderson and Gordy described the well-known lateral tarsal strip procedure, which involves shortening and repositioning the inferior crus of the lateral canthus to the periosteum of the lateral orbital rim.<sup>9</sup> The

advantages of this technique over other horizontal eyelid shortening procedures include minimal visible scarring, lower incidence of symptomatic trichiasis, preservation of the tarsal plate, and restoration of lateral canthal fixation. The tarsal strip is constructed by separating the anterior and posterior lamella, releasing the lower eyelid retractors, and removing the eyelash follicles, mucocutaneous junction, and conjunctival epithelium. The size of the lateral tarsal strip is determined by the degree of horizontal laxity of the lower eyelid, and fixation of this strip to the lateral orbital periosteum creates a secure attachment that can be utilized to reform the lateral canthal angle.

A lateral canthotomy is performed to horizontally divide the lateral canthal tendon spanning from the canthal angle to the lateral orbital rim. The inferior crus of the canthal tendon is then visually or mechanically isolated and divided to complete a cantholysis. Successful inferior cantholysis results in a fully mobile lower eyelid margin freed from all lateral attachments. Care is taken to ensure that the upper arm of the canthal tendon remains intact. The required amount of horizontal shortening is determined by pulling the lower eyelid laterally until the desired tension is achieved, and the lower eyelid is marked where it intersects with the lateral canthal angle. A subciliary incision is made and a skin-muscle flap is elevated. Next, the anterior and posterior lamellae of the eyelid are separated at the gray line and the pilosebaceous units (anterior margin and eyelash follicles) are excised to expose the underlying tarsus. The lower eyelid retractors and conjunctiva are then divided at the tarsal base and the palpebral conjunctival mucosa of the tarsal strip is removed. The conjunctiva on the posterior lamella of the tarsal strip can either be scraped with a scalpel or ablated using electrocautery. An excessively long tarsal strip may be slightly shortened by transecting its distal end. The resulting strip is then secured to the periosteum along the inside of the lateral orbital rim (Fig. 12.6.7). Multiple types of sutures have been used to attach the tarsal strip, including permanent Prolene (polypropylene) or Mersilene (polyester) sutures and dissolving sutures such as Vicryl (polyglactin). To ensure proper positioning and contour of the lateral canthus and eyelid margins, care is taken to place the sutures under the upper crus of the canthal tendon so that the medial edge of the tarsal strip sits adjacent to the canthal incision of the upper eyelid without excessively tightening the lower eyelid. If necessary, the tarsal suture is adjusted or replaced if the position and shape of the eyelid or canthal angle are not appropriate. Next, the lateral canthal angle is reformed using a 6-0 Vicryl (polyglactin) suture that joins the upper and lower eyelid margins and orbicularis. Lastly, the overlying skin is rearranged, occasionally trimmed, and sutured with 6-0 gut suture.

**Fig. 12.6.7** Tightening of the Lateral Canthal Tendon Using the Lateral Tarsal Strip Procedure.

### Medial Spindle Procedure With Rotational Suture

In 1985, Nowinski and Anderson described the medial spindle procedure for involutional medial ectropion.<sup>10</sup> This procedure can be used in conjunction with the lateral tarsal strip procedure if medial ectropion is not fully correctable with horizontal tightening of the eyelid. In this procedure, a defect is created in the posterior lamellae at the medial eyelid and the lower eyelid retractors are advanced to mechanically rotate the eyelid using sutures that are passed through the anterior lamellae. Occasionally this procedure can be performed as a stand-alone treatment for patients with medial ectropion without significant horizontal eyelid laxity and for patients with mild medial cicatricial ectropion due to the vertical anterior lamellar shortening that improves after resection of any redundant medial conjunctiva and medial eyelid retractors.

In the medial palpebral conjunctiva, an elliptical segment of redundant conjunctiva and lower eyelid retractors is resected just below the inferior tarsal border (Fig. 12.6.8). If needed, a canalicular probe is placed in the lower canaliculus to protect the canaliculus and assist in eversion of the lower eyelid for improved exposure of the palpebral conjunctiva. A double-armed 5-0 chromic gut suture is placed in a horizontal mattress fashion for segmental advancement of the retractors to the tarsal border. Each arm of the 5-0 chromic gut suture is placed sequentially through the inferior edge of the tarsus, upper edge of the lower eyelid retractors, and then through the anterior eyelid lamella. The exit point for the rotational sutures must be inferior to the placement of the eyelid retractor suture passes to provide an appropriate rotational effect. The externalized ends of the sutures are then tied at the skin. In more severe cases, multiple sutures are placed or a larger conjunctival area is resected. However, it is important to avoid excessive conjunctival resection during the procedure to avoid cicatricial entropion or shortening of the fornix. If the eyelid does not rotate into normal position, then consider replacement of sutures or further evaluation for cicatricial anterior lamellar changes.

**Fig. 12.6.8** Medial Spindle Procedure Using a Medial Elliptical Excision. Lower eyelid retractor advancement performed by extending the incision laterally (dashed line). Inset shows placement of rotational suture.

### Lower Eyelid Retractor Advancement

Severe involutional ectropion may result from marginal external rotation that initially involves the medial lower eyelid and over time extends laterally to affect the entire eyelid due to progressive lower eyelid retractor dehiscence. Advanced cases may demonstrate tarsal ectropion, where the entire eyelid is completely everted as a consequence of severe retractor laxity, dehiscence, or disinsertion.<sup>11,12</sup> This is corrected by advancing the retractors to re-establish their attachment at the lower tarsus.<sup>13</sup> In patients with coexisting horizontal eyelid laxity, retractor advancement can be combined with a tarsal strip procedure.

A transconjunctival incision is made at the inferior tarsal border along the length of the eyelid (see Fig. 12.6.8). Redundant conjunctiva and attenuated subconjunctival tissue are resected. The lower eyelid retractors are attached along the inferior tarsal edge with use of several internal 6-0 Vicryl (polyglactin) sutures. Alternatively, externalized 5-0 chromic gut rotational sutures, tied similar to the medial spindle procedure, may be utilized if medial or punctal ectropion is present.

### Full-Thickness Pentagonal Block Resection

In patients who demonstrate horizontal eyelid laxity without significant medial or lateral canthal tendon laxity or dehiscence, a pentagonal full-thickness block resection of the eyelid can be performed to correct the laxity.<sup>14</sup> Typically this procedure is preferred in patients with ectropion and isolated eyelid lesions that could also be addressed within the margins of the block resection. In the presence of medial horizontal laxity and punctal ectropion, the pentagonal block resection can be combined with a medial spindle procedure and rotational sutures (lazy-T procedure).<sup>15</sup> Additionally, horizontal laxity with coexisting mild cicatricial ectropion can be addressed using a modified block resection that preserves the eyelid skin so that it may be used as a skin flap to provide additional anterior lamellar tissue.

An initial full-thickness incision is made perpendicular to the eyelid margin and is extended to the inferior border of the tarsus. The medial and lateral edges of the transected eyelid are overlapped to evaluate the dimensions of the eyelid resection required to correct the eyelid laxity. Based on the desired size to be resected, a second incision that is also oriented perpendicular to the eyelid margin is extended to the inferior border of the tarsus. The two eyelid incisions are then angled to meet near the inferior fornix, completing the excision and forming an eyelid defect in the shape of a pentagon. Using two or three absorbable sutures such as 6-0 Vicryl (polyglactin), the two edges of the tarsal plate are carefully aligned with partial thickness sutures (Fig. 12.6.9). The edges of the eyelid retractors and orbicularis inferior to the tarsal plate are aligned and sutured together using 6-0 Vicryl to close the apex of the pentagonal defect. Marginal closure

is completed using absorbable 7-0 chromic gut sutures placed through the gray line or nonabsorbable 6-0 silk sutures with long, tied-over tails. The skin is closed using 6-0 plain gut sutures. A bandage contact lens may be placed for any patient experiencing foreign body sensation caused by the marginal sutures. These marginal sutures may be removed at 7-10 days if the patient continues to experience corneal irritation.

### Cicatricial Ectropion

#### Local Skin Flaps (Z-Plasty)

Localized cicatricial changes with focal areas of traction may occasionally be treated using Z-plasty or other skin flap procedures. The Z-plasty technique is a transposition procedure that corrects localized skin shortening or scarring by rearranging skin laxity to increase the tissue length in the direction of the shortening at the expense of the tissue perpendicular to the focal defect.<sup>16</sup>

After the entire eyelid scar is marked, two additional lines equal in length to the scar line are drawn at the upper and lower borders to form 60° angles on opposing sides of the scar (Fig. 12.6.10). The resulting Z configuration is then cut, the skin flaps and surrounding tissue are undermined to release tension, and the superficial or deep scar tissue is excised. The two triangular skin flaps are transposed so that the apices are positioned at the distal ends of the initial 60° lines and closed using 6-0 sutures.

#### Full-Thickness Skin Graft

When significant skin shortage causes cicatricial ectropion, an increase in both vertical length and the overall area of the anterior lamellar tissue is required. A full-thickness skin graft addresses this diffuse anterior lamellar deficiency and commonly returns the eyelid to a normal position. It is important to consider the color and thickness of the surrounding eyelid tissue when choosing an appropriate skin graft donor site. Potential donor sites include the upper eyelid, retro-auricular area, preauricular area, and inner arm.<sup>17</sup> Commonly, this procedure is combined with a lateral tarsal strip and/or rotational suture placement.

In patients with isolated scarring, a horizontal incision is created at the upper border of the fibrotic tissue. In patients with diffuse skin shortage, a subciliary skin incision is made 2-3 mm below the lashes. Careful sharp dissection is performed along the lower eyelid tissue to release any deep cicatricial bands and still maintain a healthy recipient bed. After the surrounding lower eyelid tissue has been undermined to release all of the cicatrized regions, the lid margin is easily elevated to normal position. The lower eyelid is then maintained in normal anatomical position with the margin apposed to the globe and the residual anterior lamellar defect is

Fig. 12.6.9 Horizontal Lid Shortening With a Full-Thickness Block Resection.

Fig. 12.6.10 Z-Plasty Procedure for Lengthening Focal Cicatricial Scarring. Flaps a and b are transposed to lengthen the scar line.

**Fig. 12.6.11 Full-Thickness Skin Graft for Lower Lid Cicatricial Ectropion.** Inset shows the retro-auricular donor site.

measured. Next, the donor site is marked, and the appropriately sized graft is then harvested from the donor site. The skin graft is then thinned of excess subcutaneous tissue and fat and placed into position at the site of the defect. The skin graft is trimmed to properly match the defect margins and attached using interrupted or running 6–0 gut sutures (Fig. 12.6.11). A bolster composed of nonadherent dressing is then secured over the graft with nonabsorbable sutures to help induce successful graft integration and prevent graft dislocation and fluid collection deep to the graft. The bolster and donor site sutures are removed at the initial follow-up visit 6–8 days after surgery.

## Paralytic Ectropion

### Medial Canthoplasty

In 1951, Lee described the medial canthoplasty procedure for the treatment of epiphora caused by punctal eversion.<sup>18</sup> Subsequently, this procedure has also been utilized to treat patients with paralytic ectropion due to orbicularis muscle weakness, as commonly observed with facial palsy.<sup>19,20</sup> The medial canthoplasty joins the upper and lower medial canthal tendons to nasally displace the fixation point and provide increased support for the medial lower eyelid. This also reduces the palpebral fissure to improve lagophthalmos and reduce corneal exposure. The procedure may be performed alone in patients with mild paralytic ectropion and punctal eversion or combined with other procedures when horizontal laxity is present.

An incision is made at the upper eyelid mucocutaneous junction starting 1 mm medial to the upper punctum and extended to the medial canthal angle. A second mucocutaneous incision is made medial to the lower punctum and extended to meet the prior incision. A skin flap is then elevated over the upper and lower medial canthal tendons. Canaliculi probes may be used to identify and protect the canaliculi. Next, a thin strip mucosa of the upper and lower eyelids is excised to expose the upper and lower medial canthal tendons. The upper and lower medial canthal tendons are adjoined using two or three interrupted 6–0 or 7–0 Vicryl (polyglactin) sutures (Fig. 12.6.12). These sutures are passed through the upper palpebral portion of the orbicularis oculi, then through the upper and lower medial canthal tendons, and finally through the lower palpebral orbicularis oculi. The skin flaps are closed with interrupted 6–0 gut sutures.

### Lateral Tarsorrhaphy

A lateral tarsorrhaphy horizontally shortens the palpebral fissure by creating an adhesion between the upper and lower eyelid margins. It is commonly performed as a protective measure in patients with lagophthalmos and paralytic ectropion caused by facial palsy to reduce corneal exposure and decrease the risk of corneal ulceration.<sup>21</sup> In cases where horizontal laxity is also present, a lateral tarsorrhaphy can be combined with

**Fig. 12.6.12 Medial Canthoplasty to Improve Medial Lower Eyelid Support and Reduce Corneal Exposure.**

horizontal tightening procedures or performed as a staged procedure to address residual corneal exposure.

After the desired tarsorrhaphy length is marked, an incision is made along the gray line of the upper and lower eyelids at a depth of approximately 2–3 mm. Further undermining is then performed to free the eyelids anterior and posterior lamellae. A 1-mm strip of the posterior lamellar mucocutaneous junction is then excised from the eyelid margins. Next, partial thickness 6–0 Vicryl (polyglactin) sutures are passed through the tarsal tissue to attach the upper and lower posterior lamellar tissue (Fig. 12.6.13). Care must be taken to ensure that these sutures do not incorporate the palpebral conjunctiva to prevent any resultant postoperative irritation. The orbicularis is closed using buried interrupted 6–0 Vicryl sutures, which is followed by closure of the skin edges using interrupted 6–0 gut sutures.

## COMPLICATIONS

Complications of surgical ectropion repair include:

- Undercorrection (under tightening).
- Overcorrection (over tightening).
- Lateral canthal angle malposition.
- Eyelid margin notching or asymmetry.
- Lacrimal system damage.
- Skin or conjunctival scarring.
- Trichiasis.
- Corneal abrasion.
- Poor cosmesis.

Undercorrection results from insufficient horizontal shortening, graft shrinkage, or suture-related fixation loss, and often requires reoperation to address the undercorrection. Overcorrection is caused by aggressive eyelid shortening, over tightening of the rotational sutures during medial spindle procedures, or excessive resection of posterior lamellar tissue and retractors causing entropion or lower eyelid retraction. Although overcorrection usually improves with time as the tissue stretches, any postoperative entropion that results in trichiasis must be temporarily addressed with epilation or may require permanent treatment with cryotherapy, electrolysis, or surgical correction.

Poor alignment of the lid margins and canthal malposition may result from several procedures, including full-thickness block resection, medial

**Fig. 12.6.13 Permanent Lateral Tarsorrhaphy Procedure to Horizontally Shorten the Palpebral Fissure.**

canthoplasty, and lateral tarsorrhaphy. A full-thickness resection may result in irregular eyelid contour and notching, as well as trichiasis. Surgical repair of the eyelid notching or contour irregularities is typically preferable to improve long-term outcomes.

Damage to the lacrimal drainage system is a potential complication when medial canthal procedures are performed. Insertion of canaliculal probes and meticulous dissection near the medial canthal region are important considerations to reduce the risk of canaliculal injury. If any concern for canaliculal injury arises during the procedure, placement of a silicone stent may prevent canaliculal stenosis and any further complications.

## OUTCOME

Careful preoperative clinical evaluation and proper surgical intervention should restore the lower eyelid margin and punctum to their normal anatomical positions so that they are apposed to the ocular surface. Mild ectropion and medial punctal ectropion are usually fully corrected with a simple procedure. Advanced cases of involutional, cicatricial, or mixed ectropion often require a combination of procedures including horizontal tightening and grafting to address the deficits.

# Benign Eyelid Lesions

Ann G. Neff, Harinderpal S. Chahal, Keith D. Carter

12.7

**Definition:** Benign eyelid lesions can arise from epithelial or dermal adnexal elements. These include epithelium, hair follicles, apocrine and eccrine glands, blood vessels, and nerves. Some may appear aggressive and must be differentiated from malignancies.

## Key Features

- Three to six times more common than malignant neoplasms.
- Can occur on any skin surface, some occur most often or exclusively on the eyelids.
- May reflect local pathology or be manifestations of systemic disease.
- Many lesions appear similar and present a diagnostic challenge.

## Associated Features

- Solid or cystic.
- Epithelial or subepithelial.
- Often multiple.
- Confused with malignant neoplasms.

## INTRODUCTION

The eyelids may be affected by a wide spectrum of benign lesions. In studies that analyzed all eyelid lesions submitted for histopathological examination, benign lesions were 3–6 times more frequent than malignant neoplasms.<sup>1,2</sup> Many lesions that affect the eyelids may occur on any skin surface, but some occur exclusively or more frequently on the eyelids.

The more common benign eyelid lesions are presented here, classified by origin, with each discussion highlighting the important clinical features, differential diagnosis, pertinent systemic associations, histopathology, and treatment.

## EPITHELIAL TUMORS

A variety of histopathological changes that affect these layers of the epidermis may be observed within lesions affecting the eyelids. Hyperkeratosis, or thickening of the keratin layer, is seen clinically as an adherent scale. Parakeratosis is a form of hyperkeratosis characterized by incomplete keratinization with retention of nuclei within the keratin layer. Dyskeratosis is abnormal keratinization of cells within the squamous layer. Acanthosis, or thickening of the squamous layer, is seen commonly in proliferative epithelial lesions. Acantholysis refers to separation of epithelial cells.

Each type of epithelial tumor may exhibit some variability in its clinical picture and morphological features. In addition, different types of tumors may share similar clinical and morphological features, which results in clinical diagnostic confusion. A definitive diagnosis of these various lesions depends on histopathological examination.<sup>3,4</sup>

## Squamous Papilloma

The most common benign lesion of the eyelid is the squamous papilloma, also known as a *fibroepithelial polyp*, *acrochordon*, or *skin tag*. These lesions may be single or multiple and commonly involve the eyelid margin. Squamous papillomas characteristically are flesh colored and may be sessile or pedunculated (Fig. 12.71). Diagnosis is made by the typical clinical appearance and histological characteristics. The differential diagnosis includes seborrheic keratosis, verruca vulgaris, and intradermal nevus.

Microscopically, the lesion has finger-like projections (fronds) with a fibrovascular core, and the overlying epidermis demonstrates acanthosis and hyperkeratosis. Treatment is simple excision at the base of the lesion.

## Cutaneous Horn

A cutaneous horn is a projection of packed keratin (Fig. 12.72). This is a clinically descriptive term, not a diagnostic one. Cutaneous horn is not a distinct pathological entity but may develop from a variety of underlying lesions, including seborrheic keratosis, actinic keratosis, inverted follicular keratosis, verruca vulgaris, basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and other epidermal tumors. Because definitive therapy is dependent on the underlying cause, biopsy of the cutaneous horn (including the underlying epidermis) is required to obtain a histological diagnosis.<sup>5</sup>

## Seborrheic Keratosis

Seborrheic keratosis, also known as *senile verruca*, is a common benign epithelial neoplasm that may occur on the face, trunk, and extremities. These lesions usually affect middle-aged and older adults, occurring as

**Fig. 12.7.1 Squamous Papilloma.** (A) Typical flesh-colored, pedunculated skin tag involving the left upper eyelid. (B) Fibroepithelial papilloma consists of a narrow-based (to the right) papilloma with fibrovascular core and finger-like projections covered by acanthotic, hyperkeratotic epithelium.

**Fig. 12.7.2 Cutaneous Horn.** Note the projection of packed keratin that arises from the skin in the region of the left lateral canthus.

**Fig. 12.7.3 Seborrheic Keratosis.** Brown, stuck-on plaque, typical of seborrheic keratosis.

single or multiple, greasy, stuck-on plaques (Fig. 12.7.3). Color varies from tan to brown, and the surface is frequently papillomatous. The differential diagnosis includes skin tag, nevus, verruca vulgaris, actinic keratosis, and pigmented BCC. Seborrheic keratoses are not considered premalignant lesions. A systemic association, however, known as the *sign of Leser-Trélat*, denotes a rapid increase in the size and number of seborrheic keratoses, which may occur in patients with occult malignancy.

A variant of seborrheic keratosis, which shares a similar histopathological appearance, is dermatosis papulosa nigra, which occurs primarily in dark-skinned individuals. These lesions usually appear on the cheeks and periorbital region as multiple pigmented papules (Fig. 12.7.4).

Although different histopathological types of seborrheic keratoses exist, all lesions share features of hyperkeratosis, acanthosis, and papillomatosis.<sup>6</sup> Most lesions contain horn cysts, which are keratin-filled inclusions within the acanthotic epidermis, and pseudohorn cysts, which represent invaginations of surface keratin.<sup>7</sup> Simple excision may be performed for biopsy or cosmesis or to prevent irritation.

### Inverted Follicular Keratosis

Inverted follicular keratosis, also known as *basosquamous cell acanthoma*, usually appears as a small, solitary, papillomatous lesion on the face. It is a well-demarcated, keratotic mass that may appear as a cutaneous horn. The lesion may resemble verruca vulgaris and seborrheic keratosis—many consider it an irritated seborrheic keratosis.<sup>8</sup> Histopathology reveals hyperkeratosis and lobular acanthosis. Proliferation of basaloid cells occurs with areas of acantholysis and zones of squamous cells, often arranged

**Fig. 12.7.4 Dermatitis Papulosa Nigra.** Multiple pigmented papules involving the malar region.

**Fig. 12.7.5 Keratoacanthoma.** (A) Lesion shows typical clinical appearance; history was also typical. (B) The lesion that can be seen above the surface epithelium has a cup-shaped configuration and a central keratin core. The base of the acanthotic epithelium is blunted (rather than invasive) at the junction of the dermis.

in whorls called *squamous eddies*. Treatment is complete excision, because recurrence is common after incomplete removal.

### Keratoacanthoma

Keratoacanthoma most commonly appears as a solitary, rapidly growing nodule on sun-exposed areas of middle-aged and older individuals. The nodule is usually umbilicated, with a distinctive central crater filled with a keratin plug (Fig. 12.7.5). The lesion develops rapidly over weeks and typically undergoes spontaneous involution within 6 months to leave an atrophic scar. Lesions that occur on the eyelids may produce mechanical

**Fig. 12.7.6 Epidermal Inclusion Cyst.** This lesion appeared as a slow-growing, cystic lesion in a region of previous penetrating trauma.

abnormalities such as ectropion or ptosis and occasionally may cause destructive changes. The differential diagnosis includes SCC, BCC, verruca vulgaris, and molluscum contagiosum (MC). Patients with Muir–Torre syndrome may develop, in association with internal malignancy, multiple keratoacanthomas and sebaceous neoplasms.

Microscopically, there is cup-shaped elevation of acanthotic squamous epithelium that surrounds a central mass of keratin. Microabscesses, which contain necrotic keratinocytes and neutrophils, may be found within the proliferative epithelium. Cellular atypia may be present, making differentiation from SCC difficult. Many pathologists consider keratoacanthoma a type of low-grade SCC. Complete excision is recommended because an invasive variant exists, with the potential for perineural and intramuscular spread.<sup>9</sup> Additional treatment modalities including intralesional chemotherapy, topical agents, lasers, cryotherapy, and photodynamic therapy have also been described.<sup>10</sup>

## Actinic Keratosis

Actinic keratosis, also known as *solar* or *senile keratosis*, is the most common premalignant skin lesion. The lesions develop on sun-exposed areas and commonly affect the face, hands, and scalp and, less commonly, the eyelid. They usually appear as multiple, flat-topped papules with an adherent white scale. The development of SCC in untreated lesions reportedly ranges as high as 20% (see Chapter 12.10).<sup>11</sup> Microscopically, actinic keratoses display hyperkeratosis, parakeratosis, and dyskeratosis. Atypical keratinocytes in the deep epidermal layers often form buds that extend into the papillary dermis. Management is surgical excision or cryotherapy (following biopsy).

## Epidermal Inclusion Cyst

Epidermal inclusion cysts appear as slow-growing, round, firm lesions of the dermis or subcutaneous tissue. Eyelid lesions are usually solitary, mobile, and less than 1 cm in diameter. These cysts usually arise from traumatic implantation of surface epidermis (Fig. 12.7.6). Cysts may become inflamed with a foreign body granulomatous reaction.

Diagnosis is based on the clinical appearance and histopathology. Differential diagnosis includes dermoid cyst, pilar cyst, and neurofibroma. Microscopically, the cyst is filled with keratin and is lined by a keratinizing, stratified squamous epithelium. Adnexal structures are not present in the cyst wall.<sup>12</sup> Treatment is complete excision, preferably of the entire cyst wall, to prevent recurrence.

## Pilar Cyst

Pilar cysts, formerly known as *sebaceous cysts*, are smooth, round, movable dermal or subcutaneous masses, clinically identical to epidermal inclusion cysts. The differentiation within these cysts is thought to be toward hair keratin.<sup>13</sup> These cysts tend to occur in areas with large numbers of hair follicles and are found most commonly on the scalp. They may occur occasionally in the periocular region, particularly in the brow or along the

**Fig. 12.7.7 Dermoid Cyst.** Cystic, subcutaneous lesion in the right upper lid and brow region, attached to the underlying frontozygomatic suture.

eyelid margin. Histopathology reveals an epithelium-lined cyst, with palisading of the basal layer. The lining lacks a granular layer, unlike that of epidermal cysts. Eosinophilic material within the cyst comprises desquamated cells and keratin and commonly calcifies. Cyst rupture may occur and incite a foreign body granulomatous response. Treatment is complete surgical excision; incomplete excision may result in recurrence.

## Epidermoid and Dermoid Cysts

Although generally considered in discussions of orbital lesions (see Chapter 12.10), epidermoid and dermoid cysts are included here because they may appear as an eyelid mass. These cysts can occur as superficial, subcutaneous, or deep orbital lesions. Both are choristomas (composed of tissue not usually found at the site) that are firm, slowly enlarging, nontender masses, most commonly in the lateral upper eyelid and brow region (Fig. 12.7.7). Superficial lesions usually are recognized during early childhood.<sup>14</sup> These cysts presumably occur secondary to entrapment of skin along embryonic closure lines. Attachment to underlying bony sutures often is present (see Chapter 12.1). Lesions may extend posteriorly into the orbit.

Microscopically, both dermoid and epidermoid cysts are lined by a stratified squamous keratinizing epithelium. Dermoid cysts also contain adnexal elements in the cyst wall, including hair follicles and sebaceous and eccrine glands. Treatment is complete surgical excision. Preoperative orbital imaging is indicated if the entire cyst cannot be palpated or if orbital extension is suspected. Complete excision eliminates the potential for cyst rupture, which can produce secondary foreign body granulomatous inflammation.

## ADNEXAL TUMORS

Lesions of adnexal origin arise from the epidermal appendages, which include the sebaceous glands of Zeis, meibomian glands, pilosebaceous units (consisting of hair follicles and associated sebaceous glands), eccrine sweat glands, and apocrine sweat glands of Moll.

## Benign Lesions of Sebaceous Origin

Sebaceous lesions of the eyelid may arise from several sources: the glands of Zeis, found in association with the eyelashes; the meibomian glands, located within the fibrous tarsal plates; and sebaceous glands, associated with hair follicles of the eyebrows and on the cutaneous surfaces of the eyelids. The sebaceous glands create their secretions by a holocrine mechanism in which the central cells undergo disintegration and subsequent extrusion into a common excretory duct.

### Milia

Milia form as multiple firm, white lesions that range between 1 to 4 mm in diameter. They usually appear on the face and commonly affect the eyelids, nose, and malar region (Fig. 12.7.8). Lesions may occur spontaneously or secondarily due to trauma, radiotherapy, skin infection, or bullous diseases. Occlusion of pilosebaceous units with retention of keratin is thought to be the causative mechanism. Histopathology reveals a dilated, keratin-filled hair follicle, with compression and atrophy of the adjacent sebaceous glands. Treatment includes simple incision, electrodesiccation of the surface, or puncture and expression of the contents.

### Sebaceous Adenoma

This uncommon lesion usually appears in the elderly as a solitary, yellow papule, with a predilection for the eyelid and brow. The importance of

**Fig. 12.7.8 Milia.** Multiple small white lesions that affect the upper and lower eyelids.

**Fig. 12.7.9 Eccrine Hidrocystoma.** Cystic lesion involving the left lower eyelid margin. The lesion was filled with translucent fluid.

this and other benign sebaceous neoplasms is the association with internal malignancy, known as the Muir–Torre syndrome. Even a single cutaneous sebaceous neoplasm may be significant, so patients should be evaluated accordingly.<sup>15</sup> Patients with this syndrome also may develop multiple keratoacanthomas. Microscopically, the sebaceous adenoma is a well-circumscribed lesion with lobules containing an outer layer of basal germinal cells that become lipidized centrally. Treatment is complete surgical excision, because incompletely excised lesions commonly recur.

### Benign Lesions of Eccrine Origin

The eccrine sweat glands are found throughout the cutaneous surface of the eyelids. They are composed of three segments, including an intradermal secretory coil, an intradermal duct, and an intraepidermal duct.

#### Eccrine Hidrocystoma

Eccrine hidrocystomas, also known as *sudoriferous* or *sweat gland cysts*, appear as solitary or multiple small nodules on the eyelids. The overlying skin is shiny and smooth, and the cyst usually is translucent and fluid filled (Fig. 12.7.9). Eccrine hidrocystomas are thought to be ductal retention cysts, which tend to increase in size in hot, humid weather. The differential diagnosis includes apocrine hidrocystoma and epidermal inclusion cyst. Histopathology reveals a dermal cyst lined by a double-layered cuboidal epithelium without papillary infoldings. Treatment is complete excision.

#### Syringoma

The syringoma is a common adnexal tumor arising from adenomatous proliferation of the intraepidermal duct of eccrine glands. They occur primarily in young women, occurring as multiple, small (1–3 mm diameter), skin-color to yellowish papules distributed symmetrically on the lower eyelids and cheeks. Microscopically, syringomas contain ducts lined by double-layered cuboidal epithelium embedded in a dense fibrous stroma. The ducts may taper to a solid core of cells to produce a comma-shaped or

**Fig. 12.7.10 Apocrine Hidrocystoma.** Cystic lesion filled with milky fluid, involving the right lower eyelid margin.

“tadpole” configuration.<sup>16</sup> Rarely, syringomas can undergo malignant transformation. Treatment modalities include surgical excision, electrodesiccation, and carbon dioxide laser.<sup>17</sup>

#### Chondroid Syringoma

Chondroid syringoma, also known as a *pleomorphic adenoma* or *mixed tumor of the skin*, most commonly occurs in the head and neck region and, rarely, may involve the eyelid.<sup>18</sup> It appears as a 0.5–3 cm in diameter, asymptomatic, dermal nodule. The lesions are thought to arise from eccrine sweat glands and owe their name to the mixture of sweat gland and cartilaginous elements. Differential diagnosis includes epidermal inclusion cyst, pilar cyst, neurofibroma, and pilomatrixoma. Microscopically, it is identical to pleomorphic adenoma (mixed tumor) of the lacrimal gland. Ducts lined with an inner secretory layer and an outer myoepithelial layer are embedded in a stroma with areas of chondroid metaplasia. Treatment is surgical excision. Malignant variants have been reported.

### Benign Lesions of Apocrine Origin

The apocrine glands of Moll are found along the eyelid margin in association with the eyelash follicles. They are modified sweat glands that contain a secretory coil, an intradermal duct, and an intraepithelial duct. Their secretions are produced by decapitation of the secretory cells.

#### Apocrine Hidrocystoma

Apocrine hidrocystoma, also known as *cystadenoma*, usually appears as a solitary, translucent cyst on the face, sometimes at the eyelid margin. The cyst is usually small (less than 1 cm in diameter) and filled with clear or milky fluid, with shiny, smooth overlying skin (Fig. 12.7.10). Lesions may display a bluish coloration, attributed to the Tyndall effect. Unlike the eccrine variety, these lesions are thought to be proliferative in origin and do not increase in size in hot weather. The differential diagnosis includes eccrine hidrocystoma and cystic BCC. An association has been reported, thought to represent an ectodermal dysplasia, in which patients display multiple apocrine hidrocystomas, hypodontia, palmar–plantar hyperkeratosis, and onychodystrophy.<sup>19</sup>

Histopathology reveals a dermal cyst with papillary infoldings, lined by an inner secretory layer with eosinophilic columnar cells and an outer myoepithelial layer. Treatment is usually by complete excision. Larger or multiple lesions may be treated by chemical ablation with trichloroacetic acid.<sup>20</sup>

#### Cylindroma

Cylindroma, presumably of apocrine origin, may occur on the eyelid or brow. It usually appears as a dome-shaped, skin-colored or pinkish red dermal nodule (Fig. 12.7.11). Solitary lesions usually occur in adulthood in the head and neck region and may appear similar to a pilar or epidermal inclusion cyst. Multiple lesions are inherited in an autosomal dominant fashion and usually appear on the scalp, where extensive involvement is referred to as a *turban tumor*. Multiple lesions have been associated with trichoepitheliomas. Microscopically, the cylindroma consists of islands with large, pale-staining cells centrally and small, cuboidal cells peripherally, surrounded by an eosinophilic basement membrane. Treatment is surgical excision.

**Fig. 12.7.11 Cylindroma.** Multiple, pinkish red dermal nodules involving the eyelids, forehead, nose, and malar region.

**Fig. 12.7.12 Pilomatrixoma.** Reddish nodule arising from the left lower eyelid.

## Benign Lesions of Hair Follicle Origin

Benign lesions of hair follicle origin are rather rare tumors, often confused clinically with BCC, the most common malignant eyelid lesion. Confirmation of diagnosis by incisional biopsy is helpful for suspicious-looking lesions, which allows less extensive resection of lesions confirmed as benign.<sup>21</sup>

### Trichoepithelioma

Trichoepithelioma is a tumor of hair follicle origin with a predilection for the face. The solitary lesion tends to occur in older individuals as an asymptomatic, flesh-colored to yellowish, firm papule that rarely ulcerates.

Multiple lesions, also known as *multiple benign cystic epithelioma* or *Brooke's tumor*, are inherited in an autosomal dominant pattern with variable penetrance. Lesions appear during adolescence as multiple firm nodules involving the face and the scalp, neck, and trunk. They may increase in size and number but rarely ulcerate. Diagnosis is made by the clinical appearance, family history, and histopathology. Differential diagnosis includes basal cell nevus syndrome, in which lesions tend to ulcerate more frequently (see Chapter 12.10).

Histopathology reveals multiple keratin-filled horn cysts surrounded by islands of basaloid cells that display peripheral palisading. The abundant fibrous stroma is well demarcated from the surrounding dermis. Lesions may histologically resemble BCC, and rare reports of transformation to BCC exist.<sup>22</sup> Treatment includes surgical excision of solitary lesions and cryosurgery or laser for multiple lesions.

### Trichofolliculoma

Trichofolliculoma is a fairly well differentiated hamartomatous lesion, usually appearing as an asymptomatic, solitary, flesh-colored nodule during adulthood on the face or scalp. A central umbilication usually is present, which is the opening of a keratin-filled follicle. Small white hairs may protrude from the central pore and are suggestive of the diagnosis. The lesion may be confused clinically with a pilar cyst, nevus, or BCC. Histopathology reveals a dilated follicle, filled with keratin and hair shafts, and lined by stratified squamous epithelium continuous with the epidermis. Surgical excision is curative.

### Trichilemmoma

Trichilemmoma is a tumor that arises from the outer hair sheath. A solitary lesion generally appears during adulthood as an asymptomatic, flesh-colored, nodular, or papillomatous lesion. The nose is the most common site of occurrence, followed by the eyelid and the brow. The lesion may appear as a cutaneous horn or may resemble verruca vulgaris or BCC.

Multiple trichilemmomas are a marker for Cowden's disease, or multiple hamartoma syndrome, a rare genodermatosis inherited in an autosomal dominant fashion. In addition to the facial trichilemmomas, patients may develop acral keratoses and oral papillomas. Patients are at increased risk of developing breast and thyroid carcinoma, as well as multiple hamartomas. The mucocutaneous lesions usually precede the onset of malignancy.

Microscopically, glycogen-rich cells with clear cytoplasm proliferate in lobules, with peripheral palisading and a distinct basement membrane.

Hair follicles may be present. Treatment is surgical excision, cryosurgery, or laser.

### Pilomatrixoma

The pilomatrixoma, also known as the *calcifying epithelioma of Malherbe*, is a benign tumor of hair matrix origin.<sup>23</sup> The lesion tends to occur in children and young adults on the head and upper extremities. Lesions may occur in the periorbital region, particularly the upper eyelid and brow.<sup>24</sup> Usually a solitary lesion, it appears as a solid or cystic, mobile, subcutaneous nodule with normal overlying skin. It is firm, irregular, often reddish blue, and may contain chalky white nodules (Fig. 12.7.12). Histopathology reveals islands of basophilic epithelial cells, which transform into shadow cells located more centrally. Most tumors contain masses of calcified shadow cells, which may incite a giant cell granulomatous response. Rare cases of malignant transformation have been reported. Treatment is surgical excision.

## VASCULAR TUMORS

### Capillary Hemangioma

The capillary hemangioma, also known as a *benign hemangioendothelioma*, is a common vascular lesion of childhood. It occurs in 1%–2% of infants and is the most common orbital tumor found in children. Girls are more commonly affected than boys, with a 3:2 ratio. A periorbital hemangioma may appear as a superficial cutaneous lesion, subcutaneous lesion, deep orbital tumor, or combination of these types. Approximately one-third of lesions are visible at birth, with the remainder manifest by 6 months of age. There is typically an initial rapid growth phase within 6 months of diagnosis, followed by a period of stabilization and subsequent involution over several years. It is estimated that approximately 75% regress to some extent by the time the child reaches 7 years of age.

The classic superficial lesion, the strawberry nevus, appears as a red, raised, nodular mass that blanches with pressure (Fig. 12.7.13). It may first be seen as a flat lesion with telangiectatic surface vessels. A subcutaneous lesion appears as a bluish purple, spongy mass. Deep orbital lesions may cause proptosis and globe displacement with no associated cutaneous findings.

The most common ocular complication is amblyopia, which may result from occlusion of the visual axis, or from anisometropia due to induced astigmatism. Strabismus may occur secondary to the amblyopia or be caused by orbital involvement with restriction of ocular motility.<sup>25</sup>

Lesions that involve the eyelid and anterior orbit usually can be diagnosed by clinical findings. The differential diagnosis of orbital lesions includes rhabdomyosarcoma, neuroblastoma, encephalocele, lymphangioma, and inflammatory masses (see Chapter 12.10). Ultrasonography, computed tomography, and magnetic resonance imaging may aid in diagnosis and in determining the extent of involvement (see Chapter 12.3).

Microscopically, the early proliferative phase of the lesion contains lobules of plump endothelial cells separated by fibrous septa, with frequent mitotic figures and small, irregular vascular lumina. Mature lesions contain more prominent vascular structures and flatter endothelial cells

**Fig. 12.7.13 Capillary Hemangioma.** (A) Superficial, raised, red mass involving the right upper eyelid. (B) High magnification of endothelial cells.

diminished in number. As regression takes place, progressive fibrosis occurs, with thickening of the fibrous septa and replacement of endothelial lobules by adipose tissue. Atrophy of the vascular component of the lesion eventuates.

Because most capillary hemangiomas undergo spontaneous regression to some extent, treatment generally is reserved for patients who have specific ocular, dermatological, or systemic indications for intervention. Various management modalities have been advocated, each with potential significant risks, which are beyond the scope of this discussion. Ocular indications include amblyopia, compressive optic neuropathy, and proptosis with globe exposure. Previous treatment modalities have included intralesional corticosteroid injection,<sup>26</sup> systemic corticosteroids, radiotherapy, laser therapy, systemic interferon, and surgery. More recently, however, systemic propranolol has emerged as the treatment of choice as a relatively safe and effective agent in inducing lesion regression.<sup>27,28</sup> Surgery should be considered for localized, noninfiltrative lesions, or for those that fail to respond medically.<sup>29</sup> Amblyopia should be treated with appropriate patching and spectacle correction, as indicated.

### Lymphangioma

Lymphangiomas may involve the eyelid, conjunctiva, or orbit. Lesions often appear at birth or early in childhood and only occasionally in adulthood. They often are poorly circumscribed, with an infiltrative growth pattern. Eyelid involvement may occur as a superficial lesion with multiple cystlike excrescences or as a complex of channels that cause lid thickening and distortion. Hemorrhage into the lesion may occur to produce a hematoma when the eyelid is involved or proptosis when orbital lesions are present (see Chapter 12.10). Biopsy may be needed for definitive diagnosis. Microscopically, dilated, thin-walled vascular spaces lined by endothelial cells are present. Surgical excision is indicated for cosmesis or eyelid malposition. Large lesions may be difficult to manage due to extensive infiltration. The use of intralesional sclerosing agents, oral sildenafil, and subtotal surgical resection have been recently described as effective treatment modalities.<sup>30</sup>

### Nevus Flammeus

Nevus flammeus, also known as a *port-wine stain*, presents as a flat, purple, vascular lesion, usually unilateral and in the distribution of a branch of the

**Fig. 12.7.14 Nevus Flammeus.** Flat, purple, vascular lesion involving the skin of the face.

trigeminal nerve (Fig. 12.7.14). It is congenital and does not undergo spontaneous regression. If associated with ocular and leptomeningeal vascular hamartomas, it represents Sturge–Weber syndrome. Ocular manifestations of this syndrome include diffuse choroidal hemangioma, ipsilateral glaucoma, and serous retinal detachment. Histopathology of the skin lesion reveals dilated, telangiectatic capillaries within the dermis. Management is primarily with cosmetics. Tunable dye laser therapy also may be used to improve the appearance of the lesion.<sup>31</sup>

### Pyogenic Granuloma

Pyogenic granuloma is the most common acquired vascular lesion to involve the eyelids. It usually occurs after trauma or surgery as a fast-growing, fleshy, red-to-pink mass, which readily bleeds with minor contact (Fig. 12.7.15). Lesions also may develop in association with inflammatory processes, including chalazia. The differential diagnosis includes Kaposi's sarcoma and intravascular papillary endothelial hyperplasia, a rare endothelial proliferation. Microscopically, there is granulation tissue consisting of fibroblasts and blood vessels, with acute and chronic nongranulomatous inflammatory cells. Notably, a pyogenic granuloma is neither pyogenic nor granulomatous. Treatment is by surgical excision at the base of the lesion.

## TUMORS OF NEURAL ORIGIN

### Neurofibroma

Neurofibromas most commonly are considered in the context of neurofibromatosis, in which patients often develop multiple cutaneous lesions in association with other stigmata of the disease, usually apparent by adolescence.<sup>32</sup> The neurofibromas may occur on any cutaneous surface, including the eyelid, and typically enlarge slowly over many years. They appear as soft, fleshy, often pedunculated masses (Fig. 12.7.16). Isolated cutaneous neurofibromas, often resembling intradermal nevi, may occur in individuals with no other associated abnormality.

The plexiform neurofibroma, characteristic of type 1 neurofibromatosis, often occurs as a diffuse infiltration of the eyelid and orbit. The upper eyelid is usually ptotic, with an S-shaped curvature (Fig. 12.7.17). On palpation, the lesion feels like a “bag of worms.” Histopathology reveals units of proliferating axons, Schwann cells, and fibroblasts, with each unit surrounded by a perineural sheath.

Management depends on the site and extent of disease. Isolated cutaneous lesions, unrelated to neurofibromatosis, may be excised surgically. Surgical debulking may be performed for plexiform neurofibromas that produce mechanical ptosis or cosmetic deformity. However, due to the infiltrative nature of these lesions, complete excision is usually impossible and recurrence is common.

**Fig. 12.7.15 Pyogenic Granuloma.** (A) Red mass arising from the palpebral conjunctiva and protruding over the eyelid margin. This lesion developed in association with a chalazion. (B) Vascularized tissue (granulation tissue) that consists of inflammatory cells (polymorphonuclear lymphocytes and fibroblasts) and the endothelial cells of budding capillaries.

**Fig. 12.7.16 Neurofibroma.** Note the fleshy mass on the eyelid of this patient with disseminated cutaneous neurofibromas.

**Fig. 12.7.17 Plexiform Neurofibroma.** Note the ptosis and typical S-shaped curvature of the upper lid.

**Fig. 12.7.18 Xanthelasma.** Multiple soft, yellow plaques involving the lower eyelid. Lipid-laden foam cells are seen in dermis and tend to cluster around blood vessels.

on the medial aspect of the eyelids (Fig. 12.7.18). The diagnosis often can be made clinically. Hyperlipidemia is reported to occur in approximately 50% of patients with xanthelasma,<sup>33</sup> therefore lipid serum screening is recommended. Type IIa is the most commonly associated hyperlipidemia. The differential diagnosis of atypical lesions includes Erdheim–Chester disease, a systemic xanthogranulomatous disorder that has lesions that typically appear more indurated.

Microscopically, xanthelasmas are composed of foamy, lipid-laden histiocytes (xanthoma cells) clustered around blood vessels and adnexal structures within the superficial dermis. Surrounding fibrosis and inflammation may be observed. Treatment modalities include surgical excision, carbon dioxide laser ablation, and topical trichloroacetic acid. Recurrence is common.

## XANTHOMATOUS LESIONS

Xanthomatous lesions are characterized by the presence of histiocytes that have accumulated lipid, resulting in a foamy appearance of the cytoplasm histologically.

### Xanthelasma

Xanthelasma palpebrarum is the most common cutaneous xanthoma, typically occurring in middle-aged and older adults as soft, yellow plaques

### Juvenile Xanthogranuloma

Juvenile xanthogranuloma (JXG), also known as *nevooxanthoendothelioma*, is a benign histiocytic proliferation that most commonly affects the skin. It occurs mainly in children under 2 years of age and usually appears within the first year of life. The skin lesions mostly appear in the head and neck region as elevated orange, red, or brown nodules. They typically increase in size and number initially, but subsequently regress spontaneously into an atrophic scar over months to years. Lesions that appear in adulthood are more likely to persist and often require treatment to induce regression.

The most common site of extracutaneous involvement is the eye, with a predilection for the iris.<sup>34</sup> The iris may contain localized vascular nodules or diffuse infiltration of tumor. Complications include hyphema, uveitis, and glaucoma, with resulting visual loss and phthisis. Treatment, which includes topical and subconjunctival corticosteroids, is recommended for intraocular lesions<sup>35</sup> because they rarely regress spontaneously and complications are common.

Biopsy of skin lesions helps to confirm the clinical diagnosis in patients who have cutaneous disease alone and in patients who have suspicious eye findings associated with skin lesions. Microscopically, lesions contain an infiltrate of lipid-laden histiocytes, lymphocytes, eosinophils, and Touton giant cells. Fibrosis appears in older lesions. Skin lesions may be treated by excision or corticosteroid injection if necessary.

## PIGMENTED LESIONS OF MELANOCYTIC ORIGIN

Skin lesions of melanocytic origin arise from one of three cell types:

- Epidermal, or dendritic, melanocytes, which lie between the basal cells of the epidermis.
- Nevus cells, or nevocytes, which usually form nests of cells within the epidermis.
- Dermal, or fusiform, melanocytes, which lie in the subepithelial tissues.

Melanocytes are derived from neural crest cells. Epidermal melanocytes produce melanin, which is transferred to surrounding epidermal cells, with tanning and racial pigmentation resulting from this process.

### Freckles

Freckles, also known as *ephelides*, arise from epidermal melanocytes. They appear as small (1–3 mm in diameter), tan-to-brown macules in sun-exposed areas, including the eyelids (Fig. 12.7.19). Freckles occur more commonly in light-complected individuals and darken with sun exposure. These lesions reflect melanocytic overactivity, not proliferation. Microscopically, hyperpigmentation occurs within the basal layer of the epidermis. No treatment is necessary, but sunscreen may help prevent further darkening of lesions.

### Lentigo Simplex

Lentigo simplex is another epidermal melanocytic lesion that may appear on skin and mucous membranes as small, brown macules. They usually appear during childhood and are unaffected by sun exposure. Lesions may be solitary and have an appearance similar to that of junctional nevi. Multiple lesions may be a manifestation of a systemic syndrome, such as Peutz–Jeghers. Patients who have this syndrome develop multiple lesions, often periocular and perioral in distribution, in association with gastrointestinal polyps, which may undergo malignant transformation. Multiple lesions may resemble freckles but do not change in pigmentation with sun exposure as freckles often do. Microscopically, lentigo simplex has hyperpigmentation along the basal layer of the epidermis with an increased

number of melanocytes. Elongation of the rete ridges occurs along with mild lymphocytic infiltration of the superficial dermis. Because these lesions are thought to have no malignant potential, intervention is not required.

### Solar Lentigo

Lesions of solar lentigo, also of epidermal melanocytic origin, are tan-to-brown macules found commonly in sun-exposed areas of older individuals. They are known as *senile lentigines* but may occur in younger individuals after prolonged sun exposure. These lesions are found commonly in patients who have xeroderma pigmentosum, often appearing during the first decade of life. Lesions usually have slightly irregular borders but are evenly pigmented. Initially, lesions are a few millimeters in diameter but slowly increase in size. They may resemble junctional nevi and seborrheic keratoses. Lesions should be differentiated from lentigo maligna, a premalignant condition that usually has variable pigmentation and more prominent border irregularity and notching. Biopsy should be performed on suspicious-looking lesions.

Histologically, solar lentigo lesions display hyperpigmentation of the basal layer of the epidermis with proliferation of melanocytes. More extensive elongation of the rete ridges is found in comparison with lentigo simplex. Treatment is not required unless desired for cosmetic reasons.<sup>36</sup>

### Melanocytic Nevi

Melanocytic nevi, also known as *nevocellular nevi*, are derived from nevocytes. They are extremely common lesions, especially in fair-complected individuals.<sup>36,37</sup> These lesions frequently occur on the eyelid skin and eyelid margin. The clinical appearance often is predictive of the histological type, which may be junctional, compound, or intradermal.

Lesions typically occur during childhood as small, flat, tan macules that gradually increase in size radially. Nests of nevus cells are found within the epidermis, at the dermal–epidermal junction, representing a junctional nevus. As the lesion ceases to increase in diameter in older children and young adults, nests of cells “drop off” into the dermis, forming a compound nevus. Clinically, compound nevi are slightly elevated and pigmented. Lesions further evolve as the remaining epidermal nests migrate into the dermis to produce an intradermal nevus. This lesion, most common in adults, may be dome shaped, pedunculated, or papillomatous and usually is less pigmented or amelanotic (Fig. 12.7.20). Later in life, as the nevus cells induce fibroplasia within the dermis, the cells decrease in number and are replaced by normal dermal tissue.

Diagnosis usually is based on the typical clinical appearance. Malignant transformation may occur rarely, generally in the junctional or compound stages. Thus suspicious-looking lesions that demonstrate irregular growth or appearance should be excised. Otherwise, removal of common nevi is not required unless desired for cosmesis or relief of mechanical irritation.

### Congenital Melanocytic Nevus

These lesions are derived from nevocytes and occur in approximately 1% of newborns. Lesions may be single or multiple and usually are deeply pigmented. The border often is irregular and the surface may be covered with hair. Congenital nevi that appear in a symmetrical fashion on adjacent portions of the upper and lower eyelids are referred to as *kissing nevi* and are formed as a result of melanocytic migration to the lids before separation of the embryonic eyelids (Fig. 12.7.21).

The size of congenital nevi is critical in management, because large lesions are associated with a higher risk of malignant transformation. There is controversy regarding the definition of “large” and “small” congenital nevi. Large lesions in the head and neck region commonly are defined as those greater than or equal to the area of the patient’s palm. The risk of malignant transformation is estimated at 5%.

Histologically, congenital nevi display a variety of patterns. Many lesions contain features of compound nevi, with nevus cells in the dermis and the dermal–epidermal junction. Nevus cells often extend into the deep dermis and subcutaneous tissue. Malignant melanoma usually develops within the deep dermis, which makes early diagnosis difficult. Thus any suspicious-looking lesion should be sampled for biopsy. Large lesions should be excised, but complete excision is impossible in some patients due to the size and extent of the lesion. The management of small lesions is controversial—some advocate excision of all congenital nevi.<sup>38</sup>

**Fig. 12.7.19 Freckles.** Multiple, tan-brown, small macules, involving the skin of sun-exposed areas.

**Fig. 12.7.20 Intradermal Nevus.** (A) Elevated, papillomatous lesion, amelanotic in color, involving the eyelid margin. (B) Nests of nevus cells fill the dermis except for a narrow area just under the epithelium. The nuclei of the nevus cells become smaller, thinner or spindle shaped, and darker as they go deeper into the dermis (i.e., they show normal polarity).

**Fig. 12.7.21 Kissing Nevus.** Congenital melanocytic nevus in a symmetrical fashion on adjacent portions of the upper and lower eyelids.

## Nevus of Ota

Nevus of Ota, or oculodermal melanocytosis, arises from dermal melanocytes. The lesion appears as a blue-to-purple, mottled discoloration of the skin in the distribution of the ophthalmic and maxillary divisions of the trigeminal nerve. It is usually congenital and unilateral and frequently is associated with ipsilateral ocular melanocytosis involving the conjunctiva, sclera, and uveal tract. Diagnosis is based on the typical clinical appearance.<sup>39</sup> Histopathology reveals pigmented, dendritic melanocytes throughout the dermis. Malignant degeneration may occur, particularly in white people, with the choroid the most common site of involvement.<sup>40</sup> Thus periodic dilated fundus examination is recommended.

## Blue Nevus

The blue nevus appears as a solitary blue nodule, usually less than 1 cm in diameter. The differential diagnosis includes melanoma, pigmented BCC, and vascular lesions. Microscopically, the lesion is composed of pigmented dendritic melanocytes and melanophages scattered throughout the dermis, often with fibrosis of adjacent tissue.

The cellular blue nevus is a lesion that also arises from dermal melanocytes. It is less common and usually larger than the blue nevus and appears as a solitary blue papule. Histologically, the lesion contains pigmented dendritic melanocytes interspersed with pale spindle cells. This lesion occasionally may become malignant and metastasize to regional lymph nodes.

Excision of these lesions may be performed for definitive diagnosis or cosmesis.

## INFLAMMATORY LESIONS

### Chalazion

A chalazion is a focal inflammatory lesion of the eyelid that results from the obstruction of a sebaceous gland, either meibomian or Zeis. Extravasated lipid material produces a surrounding, chronic, lipogranulomatous

inflammation. A chalazion may occur acutely with eyelid edema and erythema and evolve into a nodule, which may point anteriorly to the skin surface or, more commonly, toward the posterior surface of the lid. The lesion may drain spontaneously or persist as a chronic nodule, usually a few millimeters from the eyelid margin. Lesions also may appear insidiously as firm, painless nodules (Fig. 12.7.22). Chalazia often occur in patients with blepharitis and rosacea. These lesions may be mistaken for other more serious lesions such as malignancies.<sup>41</sup>

Diagnosis is based on the typical clinical features. Acute lesions appear similar to hordeola in appearance—differentiation is nearly impossible to make clinically. In recurrent or atypical lesions, a sebaceous gland carcinoma needs to be excluded, thus histopathological examination is important. Histopathology reveals lipogranulomatous inflammation, with clear spaces corresponding to lipid, surrounded by foreign body giant cells, epithelioid cells, neutrophils, lymphocytes, plasma cells, and eosinophils. A fibrous pseudocapsule may form around a lesion.

Treatment varies according to the stage of a lesion. Acute lesions are treated with hot compresses to encourage localization and drainage. Chronic chalazia may be treated using intralesional corticosteroid injection or surgical drainage. Vertical transconjunctival incisions allow adequate exposure of lesions and limit damage to surrounding meibomian glands. Small chalazia, which may resolve spontaneously, can be removed with incision and curettage.

### Hordeolum

A hordeolum is an acute purulent inflammation of the eyelid. An external hordeolum, or sty, results from inflammation of the follicle of a cilium and the adjacent glands of Zeis or Moll. The lesion typically causes pain, edema, and erythema of the eyelid, which becomes localized and often drains anteriorly through the skin near the lash line (see Fig. 12.7.22). An internal hordeolum occurs due to obstruction and infection of a meibomian gland. Initially, a painful edema and erythema localizes as an inflammatory abscess on the posterior conjunctival surface of the tarsus. In both external and internal lesions, cellulitis of the surrounding soft tissue may develop. Diagnosis is based on the clinical appearance and culture, with *Staphylococcus aureus* most frequently isolated. Hordeola frequently occur in association with blepharitis. Histopathology reveals an abscess or a focal collection of polymorphonuclear leukocytes and necrotic tissue.

Although the inflammatory process usually is self-limited, with drainage and resolution occurring within 5–7 days, hot compresses and topical antibiotics help confine the spread of the lesion. Rarely, incision and drainage are necessary. Systemic antibiotics are used only if significant cellulitis exists. Treatment of accompanying blepharitis is helpful to prevent the formation of new lesions.

## INFECTIOUS LESIONS

### Molluscum Contagiosum

A common viral skin disease, molluscum contagiosum (MC) is caused by a large DNA pox virus. Infection usually arises from direct contact or fomites in children and by a sexually transmitted route in adults. The

**Fig. 12.7.22 Chalazion and External Hordeolum.** (A) The medial lesion of the upper eyelid appeared as a firm, painless nodule consistent with a chalazion. The lateral lesion caused pain and eyelid erythema, subsequently becoming more localized with drainage of purulent material through the skin surface. (B) A clear, circular area surrounded by epithelioid cells and multinucleated giant cells can be seen. In processing the tissue, lipid is dissolved out, leaving a clear space.

**Fig. 12.7.23 Molluscum Contagiosum.** (A) Multiple flesh-colored nodules affecting the lower eyelid. (B) Small intracytoplasmic, eosinophilic molluscum bodies occur in the deep layers of epidermis. The bodies become enormous and basophilic near the surface. The bodies may be shed into the tear film, where they cause a secondary irritative, follicular conjunctivitis.

typical lesion appears as a raised, shiny, white-to-pink nodule with a central umbilication filled with cheesy material. Lesions may be single or multiple, but usually fewer than 20 are present. Eyelid margin lesions may produce a secondary follicular conjunctival reaction. Other ocular manifestations include epithelial keratitis, pannus formation, conjunctival scarring, and punctal occlusion. Primary conjunctival or limbal lesions occur rarely.

Diagnosis of MC usually is based on the clinical appearance of the lesion. Biopsy rarely is required in an otherwise healthy individual. The differential diagnosis includes keratoacanthoma, verruca vulgaris, squamous papilloma, milia, and SCC or BCC (see Chapter 12.8).

Patients who have acquired immunodeficiency syndrome (AIDS) often have an atypical clinical picture of MC. Disseminated disease may be present and lesions often are more confluent. Patients may have 30 to 40 lesions on each eyelid, or a confluent mass (Fig. 12.7.23). Secondary keratoconjunctivitis develops less frequently.

Histopathology of MC shows invasive acanthosis, with lobules of epithelial hyperplasia invaginating into the dermis. The epithelium at the surface degenerates and sloughs into a central cavity that opens through a pore to the epidermal surface. Intracytoplasmic inclusions containing virions, referred to as *molluscum bodies*, are round and eosinophilic in the lower layers of the epidermis. These inclusions increase in size and are more basophilic in the granular and horny layers.

Usually, MC spontaneously resolves within 3 to 12 months, but the patient may be treated to prevent corneal complications, reduce transmission, and speed recovery. Various treatment options exist, including simple incision or excision, incision and curettage, cryosurgery, and electrodesiccation. Management is more difficult in patients with AIDS because of extensive involvement and recurrences. Hyperfocal cryotherapy has been effective in these patients.<sup>42</sup>

## Verruca Vulgaris

Verruca vulgaris, or the common cutaneous wart, is caused by epidermal infection with the human papillomavirus, which is spread by direct contact and fomites. Verruca vulgaris is more common in children and young adults and may occur anywhere on the skin, occasionally on the eyelid. Lesions appear elevated with an irregular, hyperkeratotic, papillomatous surface (Fig. 12.7.24). Lesions along the lid margin may induce mild papillary conjunctivitis due to shedding of virus particles into the tear film. Patients also may develop a superficial punctate keratitis and may have pannus formation. Primary conjunctival lesions also may occur.<sup>43</sup>

Diagnosis is based on the typical appearance and is confirmed by biopsy. Histologically, papillomatosis is present, with hyperkeratosis, acanthosis, and parakeratosis. Large, vacuolated keratinocytes are seen, with deeply basophilic nuclei surrounded by a clear halo. Observation is recommended if no ocular complications occur, because most lesions are self-limiting. Treatment, if necessary, is either cryotherapy or complete surgical excision. Incomplete excision may cause multiple recurrences.

## CONCLUSION

The eyelids may be affected by a variety of benign lesions, some indicative of local pathology, others associated with or resulting from systemic pathology. Some lesions may be identified readily by the clinical appearance and behavior, but many pose a diagnostic challenge.

**Fig. 12.7.24 Verruca Vulgaris.** Skin-colored, irregular lesion with a papillomatous surface appearing on the upper eyelid.

Most important is the differentiation of benign from malignant lesions, because management often differs. Biopsy with ocular pathology consultation is, thus, warranted for any suspicious-looking lesion.<sup>3</sup> Epithelial lesions that display painless growth, irregular or pearly borders, ulceration, induration, or telangiectasis should raise concern for malignancy. Signs that herald malignant change in pigmented lesions include irregular borders, asymmetrical shape, color change or presence of multiple colors, recent changes, or diameter greater than 5 mm.

In general, biopsy should precede all extensive tumor resections, even if the clinical diagnosis seems apparent. An incisional biopsy should be

performed for the diagnosis of large lesions before definitive therapy. Small lesions may be excised for both diagnosis and treatment.

## OUTCOMES

Most benign eyelid lesions have an excellent prognosis. The treatment varies according to site, diagnosis, concurrent systemic involvement, and other factors.

# Eyelid Malignancies

Gregg S. Gayre, Gregory J. Vaughn, Richard K. Dortzbach

# 12.8

**Definition:** Cutaneous cancers that arise from the epidermis, dermis, or adnexal structures of the eyelid. Rarely, they may be metastatic from distant sites. They include a number of histologically distinct tumors from diverse skin cell types.

## Key Features

- Flat, eroded, or elevated lesion on the eyelid margin, eyelid skin, or brow.
- Nodular and well-circumscribed or irregular with indistinct borders.
- Ulcerated with a central crater or benign in appearance with some telangiectatic vessels.
- Slow, generally painless, growth.

## Associated Features

- Dilated blood vessels.
- Ectropion from skin contracture.
- Firm induration.
- Loss of eyelashes.
- Palpable preauricular nodes.
- Proptosis.
- Ptosis.
- Restricted ocular motility.
- Thickened eyelid margin.

## INTRODUCTION

Malignant lesions are common around the eyes, partly because many are induced by sun exposure or develop from sun-related benign lesions. Typically, most of these are small and grow slowly, which results in minimal concern for the patient and a low index of suspicion for the physician. Although the most common malignancies rarely metastasize, they can all be very destructive locally. Any periocular lesion that shows some growth, especially when associated with chronic irritation or bleeding, should undergo a diagnostic biopsy. Confirmation of histopathology is also mandatory before the patient is committed to a major resection or reconstructive procedure.

## BASAL CELL CARCINOMA

Basal cell carcinoma (BCC) is a malignant tumor derived from cells of the basal layer of the epidermis. The etiology is linked to excessive ultraviolet light exposure in fair-skinned individuals. Other predisposing factors include ionizing radiation, arsenic exposure, and scars. Although metastases are rare, local invasion is common and can be very destructive.

## EPIDEMIOLOGY AND PATHOGENESIS

BCC is the most common malignant tumor of the eyelids and constitutes 85%–90% of all malignant epithelial eyelid tumors at this site.<sup>1,2</sup> Over 99% of BCCs occur in white people; about 95% of these lesions occur between the ages of 40 and 79 years, with an average age at diagnosis of 60 years.<sup>3</sup> Rarely, they also may be seen in children.<sup>4</sup> BCC arises from a pluripotent stem cell in the epidermis that proliferates, amplifies, and eventually terminally differentiates.<sup>5</sup> Proposed mechanisms for BCC invasion include

enhanced tumor cell motility and collagenase content.<sup>1</sup> Having had one BCC is a prognostic factor for the development of additional lesions.

## OCULAR MANIFESTATIONS

Up to 50%–60% of BCCs affect the lower eyelid. The medial canthus is involved 25%–30% of the time. The upper eyelid is involved nearly 15% of the time, and the lateral canthus is only rarely involved (5%). On the basis of their histopathological presentation, BCCs may be classified into five basic types:

- Nodular-ulcerative.
- Pigmented.
- Morphea or sclerosing.
- Superficial.
- Fibroepithelioma.

Two additional, although very rare, types are the linear basal cell nevus and generalized follicular basal cell nevus.<sup>6</sup>

The nodular type of BCC, the most common lesion, has the classical appearance of a pink or pearly papule or nodule with overlying telangiectatic vessels. As the nodule grows in size, central ulceration may occur surrounded by a rolled border (Fig. 12.8.1). This appearance is often described as a “rodent ulcer.”

The pigmented BCC is similar to the noduloulcerative type in morphology but with brown or black pigmentation. These lesions represent the most common pigmented malignancy on the eyelids and may resemble malignant melanoma.

The morphea or sclerosing type of BCC appears as a flat, indurated, yellow–pink plaque with ill-defined borders. It may simulate a blepharitis or dermatitis. As it has a flat appearance, it may not be as clinically noticeable as others. However, this form of BCC is aggressive and may invade the dermis deeply. It characteristically occurs in the medial canthal region and may invade into the paranasal sinuses and orbit.

Superficial BCC appears as an erythematous, scaling patch with a raised pearly border. Fibroepithelioma BCC presents as a pedunculated or sessile smooth, pink nodule. Both the superficial and fibroepithelioma types typically arise on the trunk rather than the eyelid.<sup>7</sup>

**Fig. 12.8.1 Nodular Basal Cell Carcinoma of the Eyelid.** A firm, pink-colored left upper eyelid BCC is seen with raised border, superficial telangiectatic vessels, and characteristic central ulceration. These lesions are more commonly seen on the lower eyelid. (Courtesy Dr Morton Smith.)

BCC, Basal cell carcinoma; MM, malignant melanoma; SCC, squamous cell carcinoma; SGC, sebaceous gland carcinoma.

DIAGNOSIS

The diagnosis of BCC is initially made from its clinical appearance, especially with the noduloulcerative type with its raised pearly borders and central ulcerated crater. Definitive diagnosis, however, can be made only on histopathological examination of biopsy specimens.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of BCC and of other periocular malignant lesions may be divided into several categories: other malignant lesions, premalignant lesions, benign adnexal tumors and cysts, and inflammatory and infectious conditions (Table 12.8.1; see Chapter 12.7).<sup>8</sup> In many cases the diagnosis depends on histopathology.

SYSTEMIC ASSOCIATIONS

Basal cell nevus syndrome (Gorlin–Goltz syndrome) is inherited as an autosomal dominant disorder with high penetrance and variable expressivity. Basal cell nevus syndrome is rare, occurring in less than 1% of individuals with BCC.<sup>9</sup> The group of clinical findings described in 1960 as a syndrome by Gorlin and Goltz<sup>10</sup> includes:

- Multiple BCCs affecting the face, trunk, and extremities.
- Cysts of the jaw (odontogenic keratocysts).
- Skeletal abnormalities (e.g., bifid ribs).
- Neurological abnormalities (e.g., mental retardation, ectopic calcification, cerebellar medulloblastoma).
- Endocrine disorders (e.g., ovarian cysts and testicular disorders).<sup>7</sup>

Palmar and plantar pits also develop in young adulthood. The BCCs in this syndrome typically develop at puberty and have a predilection for the periorbital region and face.<sup>3</sup> Multiple lesions occur with a high rate of recurrence. Other rare BCC syndromes include Bazex syndrome, linear unilateral basal cell nevus, and Rombo syndrome.

Also, BCC may be associated with albinism, xeroderma pigmentosum, and nevus sebaceus.

Fig. 12.8.2 Nodular Basal Cell Carcinoma of the Eyelid. Basophilic nests of proliferating epithelial tumor cells are shown with characteristic peripheral, palisading nuclei and stromal reaction. (Courtesy Dr Morton Smith.)

Fig. 12.8.3 Morphea or Sclerosing Type of Basal Cell Carcinoma of the Eyelid. Strands and islands of basaloid cells are shown within a dense connective tissue matrix. (Courtesy Dr Morton Smith.)

PATHOLOGY

The BCCs may be grouped as either undifferentiated or differentiated by their histopathological appearance.<sup>6</sup> The typical histopathology of an undifferentiated BCC consists of nests, lobules, and cords of tumor cells with peripheral palisading of cells and stromal retraction (Fig. 12.8.2). Undifferentiated BCCs include the solid noduloulcerative, morphea or sclerosing, pigmented, superficial, and fibroepithelioma forms. The morphea or sclerosing form is characterized by strands of proliferating, malignant basal cells in a fibrous stroma (Fig. 12.8.3).

The adenoid and metatypical or basosquamous are the most common differentiated forms. These tumors differentiate toward glandular structures with mucinous stroma. They exhibit morphological features between those of basal cell and squamous cell carcinoma. The metatypical BCCs are more aggressive and invasive with a higher recurrence rate and potential for metastasis.<sup>11</sup>

TREATMENT

The goal of therapy is the complete removal of tumor cells with preservation of unaffected eyelid and periorbital tissues. Although nonsurgical treatments such as cryotherapy, electrodesiccation, and laser ablation are advocated by some,<sup>12</sup> surgical therapy is the generally accepted treatment of choice for removal of BCCs.<sup>13</sup> Some BCCs, especially the morphea and multicentric types, may extend far beyond the area that is apparent clinically. Recurrences are generally more aggressive, infiltrative, and destructive than the primary tumor.<sup>2</sup> Therefore, histological monitoring of tumor margins is essential. Mohs’ micrographic surgery and excisional biopsy

with frozen section control are the two basic techniques available. An incisional biopsy may be performed before definitive treatment to confirm the clinical suspicion of BCC.<sup>14</sup>

## Surgery

Mohs' micrographic surgery provides the highest cure rate with the most effective preservation of normal tissue.<sup>15,16</sup> Tissue is excised in layers that provide a three-dimensional mapping of the excised tumor. These layers are processed as frozen sections and viewed under the microscope. Any areas of residual tumor are identified, and the map is used to direct additional tumor excision.<sup>17,18</sup> This technique is particularly useful for morphea and multicentric-type BCCs in the medial canthal region, which may exhibit subclinical extension to orbital bone or sinuses. Mohs' micrographic surgery technique is somewhat limited if the tumor has extended to the plane of orbital fat. In addition, it requires the collaboration of a Mohs' surgeon trained in both the surgical technique and interpretation of the dermatopathology.

Excisional biopsy with frozen section control is also an effective way to remove BCCs and can be performed by the ophthalmologist. Several studies have reported no recurrences after excision of BCCs with frozen section monitoring.<sup>19,20</sup> However, following simple excisional biopsy without frozen section control, recurrence rates up to 50% have been reported.<sup>21</sup>

Eyelid reconstruction should be performed within 2–3 days after tumor excision. Various reconstructive surgical techniques may be used, depending on the location and size of the residual defect.

## Radiation Therapy

Radiation therapy is generally not recommended in the initial treatment of periocular BCCs.<sup>22</sup> However, it may be useful in the treatment of advanced or recurrent lesions in the medial canthal region or elsewhere. Doses are in the range 4000–7000 cGy.<sup>23</sup> Radiation therapy is less effective in treating morphea BCCs, with the likelihood of BCC recurrence following radiotherapy being higher than that for previously described surgical techniques. A recurrence rate of 12% was noted in one series following radiation therapy.<sup>24</sup> Surgical management is very difficult after radiation treatment of an affected area. Radiotherapy complications include skin atrophy and necrosis, madarosis, cicatricial entropion and ectropion, dry eye syndrome, cataract, and corneal ulceration.<sup>25</sup> Radiation therapy is contraindicated in basal cell nevus syndrome and is associated with significant complications in patients who have scleroderma or acquired immunodeficiency syndrome (AIDS).

## Cryotherapy

Cryotherapy is often used to treat BCCs outside the periorbital area but has also been shown to be effective for eyelid tumors with less than a 1% recurrence rate.<sup>26</sup> Around the eyelids it may result in eyelid notching and malpositions, symblepharon formation with fornix foreshortening, and pigmentary changes. It is associated with a higher recurrence rate than the surgical approaches. Cryotherapy is contraindicated in lesions greater than 1 cm in diameter, medial canthal lesions, morphea-like lesions, and recurrent BCC.<sup>27</sup>

## Chemotherapy and Photodynamic Therapy

Topical, intralesional, and systemic chemotherapeutic agents—including topical 5% imiquimod, 5 fluorouracil, cisplatin, doxorubicin, bleomycin, and interferon—have been used to treat BCCs.<sup>28</sup> In a more recent nonrandomized trial, imiquimod resulted in a histological clearance rate of 39.5% at 40 months.<sup>29</sup>

Photodynamic therapy may be considered as an alternative treatment for large numbers of cutaneous BCCs (e.g., basal cell nevus syndrome). It has been shown to be effective for noninvasive low-risk tumors and results in excellent cosmetic outcomes.<sup>30</sup> Recurrence rates of 9% at 12 months have been seen, but improved outcomes were achieved with pretreatment and repeat cycles.<sup>31–32</sup>

## COURSE AND OUTCOME

Complete surgical excision of BCCs is almost always curative, because these lesions rarely metastasize. Incomplete primary resection is the main risk factor for recurrence of tumor and is especially more common with

a medial canthal location or morpheaform histology.<sup>30</sup> The incidence of metastasis ranges from 0.028% to 0.55%.<sup>7</sup> Tumor-related death is exceedingly rare, but when it does occur, it is usually caused by direct orbital and intracranial extension.

Orbital invasion is rare and management can be difficult. Risk factors for orbital invasion include medial canthal location, previous recurrence, large tumor size, more aggressive histological subtype, and perineural spread. Management requires a multidisciplinary approach. Although orbital exenteration is the treatment of choice in most cases, globe-sparing techniques may be used for selected patients with adjuvant radiotherapy and chemotherapy.<sup>33</sup>

## SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) is a malignant tumor of the squamous layer of cells of the epidermis. It is much less common than BCC on the eyelids and carries a greater potential for metastatic spread.<sup>34,35</sup>

## EPIDEMIOLOGY AND PATHOGENESIS

Typically, SCC affects elderly, fair-skinned individuals. In the region of the eye it is usually found on the lower eyelid. Although SCC is 40 times less common than BCC of the eyelid, it is more common than BCC on the upper eyelid and lateral canthus.<sup>31</sup>

The exact mechanism of the pathogenesis of SCC is not known. However, environmental and intrinsic stimuli initiate a process in which cell growth and regulation are lost. Most periorbital SCCs arise from actinic lesions, but they may also arise de novo. Environmental factors may contribute to the development of SCC, including cumulative ultraviolet radiation (sun exposure), ionizing radiation, arsenic ingestion, psoralen plus ultraviolet A (PUVA) therapy for psoriasis, and the human papilloma virus.<sup>32</sup>

Intrinsic factors that contribute to the development of SCC include the autosomal recessive conditions xeroderma pigmentosum and oculocutaneous albinism. Chronic skin dermatoses, ulceration, and scarring are also associated with the development of this tumor. In fact, scarring of the skin is the most common intrinsic factor leading to SCC in black patients.<sup>33</sup>

## OCULAR MANIFESTATIONS

Typically, SCC presents as an erythematous, indurated, hyperkeratotic plaque or nodule with irregular margins. These lesions have a high tendency toward ulceration and tend to affect the eyelid margin and medial canthus. Lymphatic spread and perineural invasion are possible.

## DIAGNOSIS

The diagnosis of SCC is often suspected from the clinical appearance. However, because so many other malignant and benign processes can be confused with SCC, the diagnosis requires biopsy for histological confirmation.

## PATHOLOGY

Well-differentiated SCC exhibits polygonal cells with abundant eosinophilic cytoplasm and hyperchromatic nuclei (Fig. 12.8.4). Dyskeratosis, keratin pearls, intercellular bridges, and abnormal mitotic figures are prominent. Poorly differentiated lesions show little keratinization and fewer intercellular bridges.<sup>7</sup>

## TREATMENT

Before any therapy is planned, the clinical diagnosis of SCC should be confirmed by incisional biopsy.<sup>36</sup> Compared with BCC, SCC is a more aggressive and invasive tumor, but early SCC lesions of the eyelid rarely metastasize. Surgery, irradiation, and cryotherapy management options are similar to those described previously for BCC.

## COURSE AND OUTCOME

Wide local surgical excision, either with the Mohs' technique or under frozen section control, is usually curative. Advanced cases may be associated with metastasis to the preauricular and submandibular lymph nodes, which heralds a more guarded prognosis. Invasion of the deep orbital

**Fig. 12.8.4 Squamous Cell Carcinoma of the Eyelid.** Anaplastic squamous cells with hyperchromatic nuclei, abundant eosinophilic cytoplasm, and intercellular bridges. (Courtesy Dr Morton Smith.)

**Fig. 12.8.5 Sebaceous Cell Carcinoma of the Eyelid.** A large, firm, irregular nodule with yellowish coloration of the left upper eyelid is shown. Associated inflammation, telangiectatic vessels, and loss of cilia are observed. (Courtesy Dr Morton Smith.)

tissues may sometimes be seen and frequently requires orbital exenteration for cure.

## SEBACEOUS GLAND CARCINOMA

Sebaceous gland carcinoma (SGC) is a highly malignant neoplasm that arises from the meibomian glands, the glands of Zeis, and the sebaceous glands of the caruncle and eyebrow. It is an aggressive tumor with a high recurrence rate, a significant metastatic potential, and a notable mortality rate.<sup>34,35,37</sup>

## EPIDEMIOLOGY AND PATHOGENESIS

Although it is relatively rare, SGC is the third most common eyelid malignancy, accounting for 1%–5.5% of all eyelid cancers. It affects all races, occurs in women more often than men, and usually presents in the sixth to seventh decades, but cases in younger patients have been reported.<sup>38</sup>

The cause of SGC is unclear. However, there are reported associations that link SGC with prior radiation therapy<sup>39</sup> and with the production of nitrosamines and photosensitization from prior diuretic use.<sup>40</sup>

## OCULAR MANIFESTATIONS

The upper eyelid is the site of origin in about two-thirds of all cases, but SGC may arise from any of the periocular structures previously mentioned<sup>7</sup> and may have a variety of clinical appearances. It often presents as a firm, yellow nodule that resembles a chalazion. It may present as a plaque-like thickening of the tarsal plate with destruction of meibomian gland orifices and tumor invasion of eyelash follicles leading to madarosis or loss of lashes (Fig. 12.8.5). Also, SGC may mimic a chronic blepharoconjunctivitis,

**Fig. 12.8.6 Sebaceous Cell Carcinoma of the Eyelid.** Large, hyperchromatic neoplastic cells with vacuolated (frothy), basophilic cytoplasm are observed. (Courtesy Dr Morton Smith.)

**Fig. 12.8.7 Lipid Stain (Oil Red O) of Sebaceous Gland Carcinoma.** Tumor cells stain strongly positive (red) for lipid. (Courtesy Dr Morton Smith.)

meibomianitis, or chalazion that does not respond to standard therapies, thus the term “masquerade syndrome.”

SGC tends to invade overlying epithelium, which may form nests of malignant cells (pagetoid spread), or may result in diffuse spread that replaces the entire thickness of the conjunctiva (intraepithelial carcinoma). The carcinoma may exhibit multicentric spread to the other eyelid, conjunctiva, or corneal epithelium.<sup>7</sup> This neoplasm may spread through the canaliculus to the lacrimal excretory system and even to the nasal cavity.<sup>40</sup>

## DIAGNOSIS

The clinical appearance of SGC must be confirmed by a full-thickness wedge biopsy of the affected eyelid. Because of potential multicentric spread, multiple biopsy specimens should also be taken from the adjacent bulbar and palpebral conjunctiva and the other ipsilateral eyelid. The pathologist should be alerted to the clinical suspicion of SGC, and fresh tissue should be submitted to pathology so that special lipid stains may be performed on the specimen to confirm the diagnosis.<sup>41</sup>

## PATHOLOGY

Dysplasia and anaplasia of the sebaceous lobules in the meibomian glands are exhibited by SGC, with associated destruction of tarsal and adnexal tissues. Intraepithelial (pagetoid) spread to conjunctiva distant from the primary tumor may be observed. The intraepithelial spread may resemble SCC in situ.

Typically, SGC shows highly pleomorphic cells arranged in lobules or nests with hyperchromatic nuclei and vacuolated (foamy or frothy) cytoplasm due to a high lipid content (Fig. 12.8.6). Histologically, SGC may resemble the appearance of SCC. However, the cytoplasm in SGC tends to be more basophilic compared with the eosinophilic appearance of SCC. Also, SCC cells tend not to exhibit a regular, lobular arrangement. Four histological patterns have been described: lobular, comedocarcinoma, papillary, and mixed. Special stains for lipid (e.g., oil red O) on fresh tissue may assist in the histopathological diagnosis of SGC (Fig. 12.8.7).<sup>7</sup>

Periocular sebaceous carcinoma can be challenging to diagnose using histomorphology alone and can have overlapping features with both BCC and SCC. Immunohistochemistry can help differentiate these entities, especially epithelial membrane antigen, Ber-Ep4, androgen receptor, and adipophilin.<sup>42</sup>

## TREATMENT

Successful treatment of SGC depends largely on heightened clinical suspicion and awareness of the possible masquerade syndrome followed by early confirmatory biopsy. Wide surgical excision with microscopical monitoring of the margins is the procedure of choice.<sup>43</sup> Mohs' micrographic surgical excision may be used, but it may not be as successful as in BCC or SCC because of the possibility of multicentric and pagetoid spread. If the tumor is very large or recurrent with demonstrated spread to bulbar conjunctiva, to the other eyelid, or to orbital tissues, a subtotal or complete exenteration may be necessary.<sup>3,40</sup> If evidence of spread to regional lymph nodes is present, the patient should be referred to a head and neck surgeon for possible lymph node or radical neck dissection.

Radiation therapy may be considered as an adjunct to local surgery. However, primary treatment of the tumor with irradiation alone is inadequate. Few studies are available, but a 5-year survival of 80% with a progression-free rate of 93% has been reported following doses of 50–66.6 Gy.<sup>44</sup>

## COURSE AND OUTCOME

An invasive, potentially lethal tumor, SGC may cause extensive local destruction of eyelid tissues. It carries a risk of metastasis to preauricular and submandibular lymph nodes or may spread hematogenously to distant sites. It may invade locally into the globe, the orbit, the sinuses, or the brain. In a recent review of 60 cases mostly treated with surgical excision and cryotherapy, 88% were alive and well after a mean follow-up of 41 months. Orbital exenteration was necessary in 13%, local recurrence developed in 18%, and distant metastasis occurred in 8%.<sup>45</sup>

## MALIGNANT MELANOMA

Cutaneous malignant melanoma is an invasive proliferation of malignant melanocytes. Melanoma may also arise from the conjunctiva, where it constitutes a distinct entity (see Chapter 4.8). Cutaneous malignant melanoma may be classified into four different types<sup>7</sup>:

- Lentigo maligna melanoma (5%).
- Superficial spreading melanoma (70%).
- Nodular melanoma (16%).
- "Other," including acral lentiginous melanoma (9%).

Nodular melanoma is the most common type to affect the eyelids.<sup>46</sup>

## EPIDEMIOLOGY AND PATHOGENESIS

Cutaneous malignant melanoma of the eyelid accounts for about 1% of all eyelid malignancies.<sup>47</sup> The incidence of malignant melanoma has been increasing and causes about two-thirds of all tumor-related deaths from cutaneous cancers. The incidence increases with age but remains relatively stable from the fifth to the seventh decades.<sup>48</sup>

Risk factors for the development of malignant melanoma include congenital and dysplastic nevi, changing cutaneous moles, excessive sun exposure and sun sensitivity, family history (genetic factors), age greater than 20 years, and white race. Malignant melanoma is 12 times more common in white people than in black people and 7 times more common in white people than in Hispanic people. In contrast to BCC, a history of severe sunburns rather than cumulative actinic exposure is thought to be a major risk factor for developing malignant melanoma.<sup>48</sup>

Cutaneous malignant melanoma arises from the neoplastic transformation of intraepidermal melanocytes derived from the neural crest. Initially, a noninvasive horizontal growth phase occurs, which is followed by an invasive vertical growth phase.

## OCULAR MANIFESTATIONS

Lentigo maligna melanoma and its precursor lentigo maligna (melanotic freckle of Hutchinson) present as a flat macule with irregular borders and variable pigmentation. It may have a long in situ (horizontal growth) phase

**Fig. 12.8.8 Lentigo Maligna Melanoma (Hutchinson Freckle).** Clinical appearance of acquired pigmented lesion of the left lower lid.

in which the pigmentation extends for up to several centimeters in diameter and lasts many years. This phase is associated with variable growth and spontaneous regression of the lesion with alteration in pigmentation. It typically occurs in sun-exposed areas and commonly involves the lower eyelid and canthi (Fig. 12.8.8). Superficial spreading melanoma is typically a smaller pigmented lesion with mild elevation and irregular borders. It tends to have a more rapid progression to the invasive phase, characterized by development of nodules and induration. Nodular melanoma may present as a markedly pigmented or amelanotic nodule that rapidly increases in size with associated ulceration and bleeding. Acral lentiginous melanoma occurs on the palms, soles, and distal phalanges as well as on the mucous membranes.<sup>7,48</sup>

## DIAGNOSIS

The diagnosis of cutaneous malignant melanoma is made by clinical suspicion and confirmed with excisional biopsy and histopathological examination.

## SYSTEMIC ASSOCIATIONS

The dysplastic nevus syndrome (also known as B-K mole syndrome) is an autosomal dominantly inherited condition characterized by multiple large, atypical cutaneous nevi.<sup>49</sup> The moles appear in childhood and continue to grow through adulthood. Patients with this syndrome have a high risk of developing malignant melanoma.<sup>50</sup>

## PATHOLOGY

Lentigo maligna is hyperpigmentation in the epidermis characterized by a diffuse hyperplasia of atypical melanocytes throughout the basal cell layer. The entity is regarded as lentigo malignant melanoma when dermal invasion occurs during the transition to the vertical growth phase (Fig. 12.8.9). Superficial spreading melanoma is typified by atypical melanocytes that occur in nests or singly throughout all levels of the epidermis. Pagetoid spread into the epidermis is characteristic. A mixture of epithelioid, spindle, and nevus-like cells may be present. In nodular melanoma, dermal invasion is always present; it exhibits large, anaplastic epithelioid cells.

## TREATMENT

Wide surgical excision, with 1 cm of skin margins (when possible) confirmed by histological monitoring, is the procedure of choice for treatment of cutaneous malignant melanoma of the eyelid. Sentinel lymph node biopsy should be performed for tumors 1 mm thick or more, those with more than 1 mitotic figures per high-power field, and/or those with histological ulceration.<sup>51</sup> A metastatic evaluation is also recommended for patients who have such tumors. Cryotherapy may be useful in treating some conjunctival malignant melanomas, but it is not an effective treatment option for cutaneous malignant melanoma of the eyelid.<sup>45</sup> More

**Fig. 12.8.9 Malignant Melanoma.** Subepithelial pigmented, spindle-shaped melanoma cells invade the dermis. (Courtesy Dr Morton Smith.)

recently, topical 5% imiquimod has shown some encouraging results for periocular lentigo maligna.<sup>52</sup>

## COURSE AND OUTCOME

Prognosis and metastatic potential are linked to the depth of invasion and thickness of the tumor. Clark and associates<sup>53–54</sup> correlated prognosis with depth of invasion, characterized at five levels:

- Level 1: tumor confined to the epidermis with an intact basement membrane.
- Level 2: tumor extension beyond the basement membrane with early invasion of the papillary dermis.
- Level 3: tumor fills the papillary dermis and reaches the interface between the papillary and reticular dermis.
- Level 4: tumor penetrates the reticular dermis.
- Level 5: tumor invasion of the subcutaneous tissues.

For lentigo maligna melanoma in levels 1 and 2 there is a 100% survival rate after therapy, whereas for nodular melanoma extending to level 4 there is a 65% survival rate following treatment. The survival drops dramatically to only 15% with extension of any type to level 5.<sup>55</sup>

Breslow<sup>56</sup> related prognosis to tumor thickness—malignant melanomas less than 0.76 mm thick are associated with a 100% 5-year survival rate after excision; tumors greater than 1.5 mm in thickness are associated with a less than 50% 5-year survival rate. Therefore nodular melanoma has the worst prognosis, and lentigo maligna melanoma has the most favorable prognosis of all tumor types. The Clark and Breslow systems may be used in conjunction to predict the prognosis for patients with malignant melanoma.

In a review by Tahery et al.,<sup>57</sup> malignant melanoma involving the eyelid margin was found to have a poorer prognosis than eyelid malignant melanoma that did not affect the margin. This worse prognosis was attributed to conjunctival involvement in the eyelid margin tumors.

# Evaluation and Management of Periorbital Soft Tissue Trauma

12.9

*Ivan Vrcek, Marie Somogyi, Vikram D. Durairaj*

**Definition:** Injuries varying from simple skin abrasions to more complex cases with extensive tissue loss and underlying fractures of the facial skeleton caused by blunt or penetrating facial trauma.

## Key Features

- Partial-thickness eyelid injury.
- Eyelid margin lacerations.
- Eyelid injuries with tissue loss.
- Full-thickness eyelid injury.

## INTRODUCTION

Periorbital soft tissue injuries, including blunt and penetrating trauma to the eyelids and lacrimal apparatus, are common presentations to emergency departments and outpatient ophthalmology clinics.<sup>1-3</sup> These injuries can vary from simple skin abrasions to more complex wounds that involve de-gloving facial injury with damage to the lacrimal apparatus, globe, and underlying periorbital bony anatomy. Following a thorough assessment of the patient's vital signs and overall medical stability, a thorough examination that includes a complete ophthalmic examination is required. Treatment of these injuries requires careful identification of the anatomical structures involved and a repair that focuses primarily on restoring normal function and preserving globe integrity.

Secondarily the repair should strive to recreate normal anatomy in a way that respects the aesthetic facial subunits to maximize the patient's long-term cosmesis. Postoperative care of these patients can be complex, including revision surgery to restore lacrimal function, interventions to optimize scar management, and surgical correction of chronic eyelid malposition. In this chapter, we discuss these injuries in detail with an emphasis on the diagnosis, treatment, and postoperative care of these often challenging patients.

## PREOPERATIVE EVALUATION AND DIAGNOSTIC APPROACH

### Systemic Stabilization

The evaluation and treatment of periorbital injuries begins after the patient has been stabilized and life-threatening injuries addressed. A complete and thorough assessment is required to assure that life- and limb-threatening injuries have been adequately assessed and managed before the periorbital area is addressed.

### Medical History

A complete history is obtained, with an emphasis on the time course and circumstances of the injury. In children and the elderly, consideration must be given to the possibility of nonaccidental trauma. A history consistent with injuries from high-speed projectile particles typically requires the appropriate imaging studies to determine the presence of intraocular

or intraorbital foreign bodies. Animal and human bites deserve particular attention and are managed accordingly with the administration of appropriate antibiotics.

## Examination

Once the patient is medically stable, a comprehensive ophthalmic and adnexal assessment is required. We advocate a methodical and stepwise approach to this examination. The periorbital region is first assessed, beginning with the skin envelope. Attention is directed to the presence, location, and depth of skin and subcutaneous injury. Particular emphasis is placed on a thorough examination of the eyelid margin and the medial and canthal regions because lacerations in these areas can be difficult to immediately identify. Injuries to the skin and soft tissue must be carefully documented and their dimensions recorded. Photography is often helpful for documentation in these situations. Lacerations of the eyelid margin should be carefully examined for the presence of full-thickness margin-involving lacerations. The medial canthal area must be examined for the presence of injuries to the lacrimal system and medial canthal tendon because such injuries can have long-lasting sequelae. Lateralization of the punctum is a sign that a canalicular laceration and/or damage to the medial canthal tendon is likely. Similarly, poor apposition of the eyelid to the globe medially also suggests damage to the medial canthal tendon.<sup>3,4</sup> If an injury to the lacrimal system is suspected, lacrimal probing with or without irrigation can be performed. In many cases, a knowledge of medial canthal anatomy makes probing and irrigation unnecessary. For example, if there is a full-thickness laceration medial to the punctum and the eyelid is lateralized, the likelihood of canalicular injury is extremely high.<sup>3,4</sup> The lateral canthal tendon integrity must also be assessed and repaired if indicated.

In analyzing the extent of soft tissue injury to the eyelids, it is helpful to conceptualize the eyelid in terms of anterior, middle, and posterior lamella. The anterior lamella is composed of the skin and orbicularis. The middle lamella is composed of the tarsus, lower eyelid retractions, Müller's muscle, levator muscle, and septum. The palpebral conjunctiva constitutes the posterior lamella. Immediately recognizing the lamellae involved can aid the surgeon in identifying the particular anatomical structures that must be addressed. In addition, reconstructive maneuvers often treat these lamella as functional subunits in the eyelid.

A detailed understanding of neurovascular anatomy is also required, and care must be directed to injuries that may involve branches of the facial nerve and critical periorbital vasculature.

Following assessment of the skin envelope and adnexa, the periorbital bony anatomy is assessed. This can be accomplished by carefully and methodically palpating the lateral, superior, and inferior orbital rims. The nasal sidewall is also assessed for step-offs and deformities. A low threshold for obtaining radiographic studies should be maintained as bony orbital trauma may not be immediately obvious.

The cranial nerves are examined sequentially with particular focus on the frontal and zygomatic branches of the facial nerve and cranial nerves III, IV, and VI. It is important to assess sensation in the territories of the first and second divisions of the fifth cranial nerve. Attention is then directed toward the ophthalmic portion of the examination.

The ophthalmic examination should proceed in a similar methodical stepwise fashion. Visual acuity, pupil examination, intraocular pressure testing, extraocular motility, and confrontation visual field testing are the cornerstones of a complete ophthalmic examination and should be performed in every patient where possible. Next, a complete ophthalmic examination is performed. We find it helpful to proceed methodically from

anterior to posterior. The conjunctiva and sclera are examined first with an emphasis on detecting lacerations. Examiners should be aware that large amounts of subconjunctival hemorrhage may obscure a scleral laceration, and if indications exist, a low threshold should be maintained for operative globe exploration. The cornea is examined next. Fluorescein staining is a useful adjunct, both for detection of abrasions and for exploring Seidel positivity. The anterior chamber is examined next with care taken to ascertain depth as well as the presence of foreign material, cell and flare, and synechiae. The lens is examined next. A sectoral cataract or dislocation may indicate penetrating injury. A full dilated examination is then performed to examine the vitreous and retina.

In situations where globe injury is suspected, a shield is placed over the eye in question without pressure on the eye. It is important to perform a full and comprehensive examination of the fellow eye.

Ancillary Testing

In most emergency department settings, basic laboratory studies typically have been performed. If the injury is chronic and purulent, a culture is warranted to guide antibiotic therapy. In many scenarios, radiographic testing, typically computed tomography (CT), is indicated as the test of choice. There should be a low threshold to obtain a CT scan, as bony trauma in the orbit can often go undetected.<sup>5</sup> Additionally, imaging is often very helpful in the event that retained foreign material is present in the soft tissue or the globe itself. Caution must be used if magnetic resonance imaging (MRI) is planned, as there may be retained metallic foreign material.

Documentation

All injuries are documented precisely and completely with a detailed description in the patient's charts. Photographic documentation is advised in all cases. Bullets and other projectiles must be retained and marked so that no break occurs in the chain of evidence. The medicolegal implications can be significant, so every effort must be made to complete the preoperative documentation of every injury.<sup>6</sup>

Infection Prophylaxis

Depending on the mechanism of injury, preventing infection is of the utmost concern. Although the role of antibiotic prophylaxis has been controversial,<sup>7–12</sup> we advocate thoughtful use of appropriate antibiotic prophylaxis. In the case of obviously contaminated wounds with extensive injury, thorough washout should be performed with a low threshold for the use of systemic antibiotic prophylaxis. Less extensive injuries and superficial abrasions may not require systemic antibiotics, but topical antibiotic ointment should be used. The patient should be queried regarding their tetanus immunization history and provided a tetanus vaccine if the patient is not up to date or unaware of their last vaccination (Table 12.9.1).<sup>6</sup> In the case of an animal bite, all information about the animal's history, the owner of the animal, and site of injury must be recorded and the local animal care department notified. In these situations, the standard rabies protocol must also be followed.<sup>6–8</sup>

The role of antibiotic prophylaxis in cases of animal bites has been controversial.<sup>8–12</sup> Cat bites carry a high risk for infection, mainly with *Pasteurella multocida*. The mechanism of injury, typically a deep puncture wound, increases the risk of contamination and subsequent infection. Infection

prophylaxis should be initiated with either amoxicillin/clavulanate or penicillin VK 500 mg a day for 5–7 days.<sup>8</sup> In penicillin-allergic patients, tetracycline can be used as an alternative. A more detailed discussion on dog bites can be found later, but these injuries also carry risk of infection. Thorough washout is required, and antibiotic prophylaxis should be strongly considered in all wounds that are surgically closed and in high risk injuries. Amoxicillin/clavulanate is the antibiotic of choice.<sup>8–11</sup>

Human bite injuries also carry a high risk for infection due to the large amount of bacteria present. As a result, it is necessary to provide appropriate broad-spectrum antibiotic coverage such as penicillin, amoxicillin/clavulanic acid, cephalexin, or ciprofloxacin.<sup>8–11</sup>

Almost universally following a traumatic injury, it is prudent to copiously irrigate all injured tissue with antibiotic irrigation solution. Any remaining foreign material should also be removed to prevent future infection.

Timing of Repair

The timing of surgical repair is dependent on many factors. Ideally, all injuries would be repaired almost immediately following the initial injury. First and foremost, the patient must be systemically evaluated for any signs of more life-threatening injuries. Once the patient has been cleared and thoroughly examined, every effort should be made to arrange for prompt surgical repair. The timing for anesthesia may also be dependent on the patient's last intake of food. Depending on the nature of the patient's injuries, there may be multiple specialists involved, which also takes coordination and may result in a delay. The best chance for successful restoration of function and cosmesis exists in the first surgery, so it is in both the surgeon and the patient's best interest to arrange for the personnel needed.

In some cases, the patient has more pressing systemic issues that have to be addressed first. In these circumstances, waiting 24–48 hours does not typically negatively affect the patient, but it is recommended to initiate an antibiotic regimen to prevent secondary infection of the open wound. The wound should also be kept moist with saline-soaked gauze and topical ophthalmic lubrication to prevent exposure keratopathy.

ANESTHESIA

There are many factors that influence the choice of anesthetic. First and foremost, the patient's age often dictates the type of anesthesia, with general anesthesia being the treatment of choice in pediatric patients, whereas adults may tolerate intravenous sedation with local anesthetic. Many adult injuries can even be repaired using only local anesthetic or regional anesthetic. Irrespective of the patient's age, extensive soft tissue injuries and bony fractures are often best performed under general anesthetic.

Regardless of the type of systemic anesthesia, it is always recommended to provide local infiltrative or regional anesthetic for both analgesia and hemostasis. Typically, 1%–2% lidocaine with 1:100 000 epinephrine in combination with 0.5%–0.75% bupivacaine is used to provide both immediate and long-term anesthetic, taking advantage of lidocaine's short onset of action and bupivacaine's longer duration of action. Furthermore, the addition of hyaluronidase will facilitate local infiltration of tissues with less distortion of tissue planes. Nerve blocks are an excellent adjunct to local anesthetic to provide regional coverage without excessive tissue distortion. In the periorbital region, this is successfully accomplished through supra-orbital (V<sub>1</sub>) and infraorbital (V<sub>2</sub>) nerve blocks.<sup>13</sup>

TREATMENT

General Concepts

In patients with eyelid trauma, the first step in planning reconstruction is to identify which anatomical structure(s) are violated.<sup>14</sup> In this way, one first defines the problem before developing a plan for repair. Guiding principles in reconstruction include recreating normal anatomy, restoring functional units, and secondarily, respecting aesthetic facial subunits to produce the most cosmetically acceptable result possible.<sup>15</sup> The primary function of the eyelids, for example, is protection of the globe. Depending on the degree of disruption to this protective mechanism, severe injury to the globe can result over a period of hours to days due to desiccation, ulceration, and infection.<sup>6</sup>

Conceptualizing the eyelids in terms of lamellae, as described earlier, can be helpful in devising a reconstructive plan. By identifying the lamellar deficiencies, one can identify the anatomical problem created by the injury. The reconstruction then focuses on recreating the necessary lamellae.

TABLE 12.9.1 Guidelines for Tetanus Prophylaxis in Wound Treatment

Immunization History	Clean, Minor Wound	Other Type of Wound
Uncertain history	Tetanus and diphtheria toxoids <sup>a</sup>	Tetanus and diphtheria toxoids + tetanus immune globulin
None or one previous dose	Tetanus and diphtheria toxoids <sup>a</sup>	Tetanus and diphtheria toxoids + tetanus immune globulin
Two previous doses	Tetanus and diphtheria toxoids <sup>a</sup>	Tetanus and diphtheria toxoids <sup>b</sup>
More than three previous doses	None unless the last dose is more than 10 years previously	None unless the last dose is more than 10 years previously

<sup>a</sup>Adult type; for children less than 7 years of age, DTP (diphtheria, tetanus, pertussis).

<sup>b</sup>For wounds more than 24 hours old, add tetanus immune globulin.

Adapted from Mustarde JC. Eyelid reconstruction. Orbit 1983;1:33–43.

Reconstructive surgery requires an expert knowledge of the local anatomy. In particular, understanding the blood supply to the eyelids is critical to the success of reconstructive maneuvers. Fortunately, the eyelids are exceptionally well-vascularized tissues, but preserving the integrity of the peripheral and marginal arcades must be carefully considered.

Finally, it is recommended to take advantage of the many successful, well-established techniques in eyelid reconstruction that have been utilized following tumor excision, including advancement and rotational flaps, tarsoconjunctival flaps, and periosteal flaps.<sup>6,16,17</sup>

## COMMON PATTERNS OF EYELID INJURY

### Partial-Thickness Eyelid Injuries and Abrasions

Not all periorbital injuries require surgical intervention. In some cases, wounds may be allowed to heal by second intention with close observation over time.<sup>18,19</sup> Small partial-thickness lacerations that do not involve the eyelid margin may fall in this category. Similarly, abrasions to the eyelid skin do not always require surgical intervention. Indeed, if there is epidermal tissue loss and one attempts to approximate intact epidermis, eyelid malposition and distortion may result by the alteration of normal eyelid architecture.<sup>18,19</sup>

In these situations, appropriate wound care is required to obtain an optimal result. Lubrication with ophthalmic antibiotic ointment is the mainstay of encouraging wound healing over the ensuing days. If the wound is dirty or is suspected of being contaminated, a thorough washout is recommended. Hydrogen peroxide can be used to keep the wound sterile. Excessive use of hydrogen peroxide, however, will impede wound healing.

On the other hand, sutured closure is an appropriate course of action if a superficial partial-thickness laceration exists that involves the epidermis and can be reapproximated without distorting normal architecture. In most cases, the orbicularis muscle does not require a separate layer of closure; indeed, doing so may result in architecture disruption in some situations. Typically, 6-0 gauge suture represents a suitable choice to impart the necessary strength to maintain adequate closure. The suture material to be used is dependent on a variety of variables, including the location of the laceration, the reliability and age of the patient, and surgeon preference. In our practice, lacerations that will be concealed in the eyelid crease are well suited to the use of absorbable sutures. Similarly, children and patients who may have difficulty with follow-up are good candidates for absorbable sutures. Lacerations that will not conceal well in the eyelid crease in patients who will reliably follow up may be closed with nylon or polypropylene sutures to be removed in 6-7 days. In all cases, patients are instructed to lubricate the wound with ophthalmic antibiotic ointment for at least 1 week following repair.

Wounds that violate the orbital septum should be treated as deep partial-thickness lacerations, discussed in the next section.

### Deep Partial-Thickness and Full-Thickness Eyelid Lacerations

Lacerations that penetrate the orbital septum or represent true full-thickness nonmarginal lacerations typically require timely surgical repair. These lacerations often demonstrate significant anatomical injury and infection risk. Thus we recommend repair in a sterile setting with copious washout using antibiotic solution and careful closure.

Thoughtful closure should respect anatomical planes and consider the future healing process. Each layer of the eyelid should be inspected for integrity. The conjunctiva and Müller's muscle may be approximated with buried sutures, but in many cases these layers can be carefully reapproximated without sutured closure. Although a surgeon can attempt to isolate and repair injuries to the levator, extreme care should be taken not to incorporate other layers, particularly the septum, into this closure. Incorporation of the septum can lead to severe eyelid retraction with cicatricial lagophthalmos that can lead to corneal decompensation and serious morbidity. As a general rule, the septum should be left unsutured in the repair of eyelid lacerations. In many cases it is advisable to not repair levator injuries primarily. Secondary ptosis repair is often a safer alternative.<sup>20,21</sup>

The tarsus typically extends 10 mm from the eyelid margin in the upper eyelid and 4 mm from the eyelid margin in the lower eyelid. Knowledge of this anatomy can aid the surgeon in identifying tarsus-involving lacerations. If the tarsus is involved in the laceration, the tarsus should be carefully trimmed to establish regular squared-off edges to facilitate repair without postoperative kinking or step offs.<sup>22</sup> Repair then proceeds

with partial-thickness sutures to avoid any suture contact with the ocular surface. We advocate the use of braided suture such as a 6-0 polyglactin on a spatulated needle. This needle choice minimizes trauma to this critical layer of the eyelid, and the braided suture and gauge maximize the tensile strength of the closure of this critical layer.

In most cases, orbital fat should be repositioned below the septum gently and the overlying skin should be carefully closed without incorporation of other layers. Orbicularis closure is also typically not required, as reapproximation of the overlying skin will often bring lacerated edges of the orbicularis into close proximity for future healing.<sup>20,21</sup>

### Eyelid Margin Lacerations

The repair of lacerations that involve the margin requires meticulous attention to each layer of the eyelid. Without careful closure, notching, trichiasis, and tarsal irregularities with subsequent ocular surface complications can occur. We advocate the stepwise reapproximation of these injuries in the following fashion. First, a vertical mattress 6-0 polyglactin suture is passed through the eyelid margin at the level of the tarsus. A useful landmark for identifying the tarsal plane at the eyelid margin is the space immediately posterior to the lash line and anterior to the gray line. This suture can be left temporarily untied, but the appropriate apposition should be carefully evaluated because this is the critical suture for lid margin apposition and proper wound eversion. Leaving this knot temporarily untied allows ease of access to the remainder of the tarsus. Next, partial-thickness bites through the tarsus with 6-0 or 7-0 polyglactin on a spatulated needle should be used to reapproximate the entire length of the tarsus. The next step is closure of the overlying orbicularis, which can be accomplished with single interrupted sutures. The margin suture is then tied securely, providing suitable eversion of the eyelid margin. When tying these sutures, care should be taken to trim the knots short to avoid the knots to potentially irritate the ocular surface during the healing phase. The skin is then closed according to surgeon preference (Fig. 12.9.1).<sup>6,20-22</sup>

### Eyelid Injuries With Tissue Loss

Eyelid injuries with tissue loss can pose a significant reconstructive challenge. The entire armamentarium of the reconstructive surgeon must come to bear on these injuries, including the use of rotational flaps, advancement flaps, skin grafts, periosteal flaps, and canthal release. Particular consideration should be given to the possibility of postoperative eyelid retraction, and placement of a Frost or reverse Frost suture tarsorrhaphy should be considered in these cases.

#### Tissue Loss of 0% to 25%

In most cases, full-thickness injuries with this degree of tissue loss can be closed primarily as described previously. In some situations, careful trimming of necrotic tissues or irregularities in the tarsus may be required to allow for appropriate reapproximation. These maneuvers should be performed with the intent of maximal preservation of viable anatomical tissue to facilitate repair.<sup>20-22</sup>

#### Tissue Loss of 25% to 60%

These injuries may preclude direct closure and may require advancement of surrounding tissues. As a general rule, the surgeon should focus on taking advantage of intact native anatomy. In particular, the medial and lateral canthal tendons and periosteum offer robust anchor points for advancement and rotational flaps.

When necessary, lateral canthal tendon release can facilitate the advancement of lateral eyelid tissues and even tissues lateral to the lateral canthus, such as in a Tenzel flap (Fig. 12.9.2).<sup>6,23</sup>

Periosteal flaps are also very useful in the recreation of normal anatomy in these types of injuries. Periosteal flaps have the advantage of providing robust support for the lower eyelid and the correct vector to facilitate the eyelid maintaining apposition with the globe (Fig. 12.9.3).<sup>6,24</sup>

### Full-Thickness Eyelid Injuries With Greater Than 60% Tissue Loss

#### Lower Eyelid

Lower eyelid defects of this type may be attempted to be repaired with advancement, rotational, or periosteal flaps, but such methods may be unsuccessful in large defects. General principles of closure in these situations are similar to those involved in reconstructive surgery following

**Fig. 12.9.1 Direct Closure of a Marginal Eyelid Laceration.** The suture is placed precisely in the plane of the meibomian glands at the eyelid margin, approximately 2 mm from the wound edges and 2 mm deep. This placement should provide adequate margin eversion. Partial-thickness lamellar sutures are placed across the tarsus and tied anteriorly. The anterior skin and muscle lamella is closed with fine sutures, and these are tied over the long marginal sutures to prevent corneal touch.

**Fig. 12.9.2 Repair of a Lower Eyelid Defect With the Tenzel Myocutaneous Flap.**

**Fig. 12.9.3 A Periosteal Flap Can Be Rotated to Supplement the Lateral Posterior Lamella in Eyelid Reconstruction.** (Courtesy Regents of the University of California, 1997; reprinted with permission.)

eyelid skin cancer resection. In particular, the Hughes tarsoconjunctival flap is a two-stage procedure that is very well suited to centrally located full-thickness lower eyelid defects.<sup>25</sup> In most cases, a full-thickness skin graft is required to supply the anterior lamella and can be harvested from the contralateral eyelid or pre- or postauricular skin (Fig. 12.9.4).<sup>6</sup>

Alternatively, free tarsoconjunctival flaps or transposition tarsoconjunctival flaps have been shown to be very effective in these types of reconstructions.<sup>26</sup> These flaps may require advancement of skin for anterior lamellar closure.

For very large defects, a cervicofacial advancement flap such as that described by Mustarde may be required (Fig. 12.9.5).<sup>6,27</sup>

### Upper Eyelid

Large injuries of the upper eyelid with tissue loss pose perhaps the highest degree of difficulty in repair. There are numerous considerations in the repair of these injuries including the status of the levator

muscle, potential septal scarring and retraction, and globe protection. It has been said that one can live without a lower eyelid, but the globe cannot survive without an upper eyelid.<sup>28</sup> Repair of these defects follows the general principles outlined earlier—the recreation of normal anatomy with an emphasis on globe protection. Careful consideration of both vertical and horizontal tension is required to avoid retraction and ptosis respectively.

In some cases, a large lateral or horizontal advancement of an upper eyelid tarsoconjunctival flap can be used to recreate the posterior lamella. A laterally based periosteal flap may supply lateral support and horizontal length in these situations. A full-thickness skin graft can be used to supply the anterior lamella.<sup>28</sup>

The Cutler–Beard flap has been used to repair very large defects in the upper lid when other maneuvers are not possible.<sup>29</sup> This two-stage procedure uses the full thickness of the distal lower eyelid to repair the proximal upper eyelid. The flap is passed under a bridge of intact lower eyelid margin. The second stage is used to divide the flap and open the palpebral aperture (Fig. 12.9.6).<sup>6</sup> This technique is limited by the fact that the tarsus is typically 4 mm in vertical dimension in the lower lid. The procedure must maintain a portion of this tarsus in the lower eyelid to preserve lower eyelid integrity, thus the upper eyelid is left with deficient tarsus and therefore structural instability. This frequently leads to chronic postoperative sequelae in the reconstructed upper eyelid, but the procedure does allow for globe protection.

### Postoperative Care

As with most facial trauma, patients with eyelid injuries often require frequent early postoperative evaluation. In the early phase, evaluation should focus on wound integrity and any signs or symptoms of infection. Antibiotic prophylaxis has been a point of controversy, but we advocate a low threshold for the use of prophylactic systemic antibiotic use in contaminated wounds. In addition, lubrication with antibiotic ointment is typically indicated. Antibiotic ointment functions not only as a lubricant and disinfectant but also speeds re-epithelialization in areas that are left to heal by second intention.

As stated earlier, we advocate the use of Frost and reverse Frost suture tarsorrhaphies in complex eyelid reconstruction to aid in minimizing postoperative eyelid retraction. We typically remove such tarsorrhaphies at 7–10 days postoperatively.

After the early postoperative phase, patients with eyelid trauma should be followed for the development of potential complications such as lacrimal dysfunction, cicatricial eyelid retraction, and hypertrophic scarring. All patients should be counseled on sun avoidance and sunscreen use to minimize scarring. In the event of future eyelid malposition or lacrimal dysfunction, these issues can be addressed if clinically indicated.

During the cicatricial phase of healing (commonly 3–4 weeks following repair), it may be beneficial to advocate massage or other scar-modulating therapies such as off-label injection of Kenalog or 5 fluorouracil (5-FU). The use of these interventions must be individualized and advocated with care with appropriate informed consent. The biochemical underpinning of these maneuvers exists through their disruption of fibroblast activity. During the cicatricial phase of healing, fibroblasts are depositing cartilage in a linear, nonmeshlike fashion. Downregulating fibroblast activity, either mechanically through stretch or chemically, can be helpful in reducing this robust collagen deposition that is a feature of the cicatricial phase of healing.<sup>30</sup>

**Fig. 12.9.4 The Hughes Tarsalconjunctival Flap Procedure.** (A) The lower eyelid defect is examined to estimate the width of the flap. (B) The flap is dissected from the posterior lamella of the upper eyelid. At least 4 mm of tarsus must remain along the upper eyelid margin to enable stabilization. (C) A skin graft can provide adequate anterior lamella of the lower eyelid. (D) After 4–6 weeks the flap is divided to restore the eyelid margins. (Courtesy Regents of the University of California, 1997; reprinted with permission.)

**Fig. 12.9.5 Repair of Large, Full-Thickness Lower Eyelid Defects With the Mustarde Myocutaneous Flap.**

We typically defer further reconstructive surgery until after the cicatricial phase of healing is complete—typically a minimum of 3 months after initial repair. Exceptions to this practice include situations in which the ocular surface is at risk of decompensation, severe desiccation, ulceration, or scarring. Deferring surgery until after the wounds are mature allows for a higher chance of future success and more facile dissection planes.<sup>30</sup>

### Late Repair of Eyelid Injuries

Late repair of eyelid injury is often plagued by cicatricial processes that involve cicatricial elements of eyelid anatomy. In the upper eyelid, levator scarring is common, resulting in tethered ptosis or cicatricial lagophthalmos. The medial and lateral canthal attachments may require repair. If eyelid margin trauma is neglected, notching is a frequent occurrence.

**Fig. 12.9.6 The Cutler-Beard Bridge Flap.** A full-thickness flap of lower eyelid tissue is advanced beneath a marginal bridge into the upper eyelid defect. After 3–4 weeks the flap is cut at the appropriate level and the lower lid is repaired. (Courtesy Regents of the University of California, 1997; reprinted with permission.)

The evaluation of these patients should proceed as described earlier with a systematic evaluation of the eyelids and adnexal tissues followed by evaluation of the globe.

In situations where late repair is required, the standard guidelines remain unchanged: The focus is on restoring function by recreating normal anatomy. The secondary goal is to optimize cosmesis.

Areas of eyelid margin notching can often be excised and repaired as a full-thickness margin-involving laceration as described earlier. Extensive cicatricial processes surrounding the levator complex may require extensive debridement to recreate normal functioning anatomy. Addressing lower eyelid retraction may require lateral canthal support, release of cicatrix, medial canthal support, and midfacial advancement and support. Skin grafting may even be necessary in some cases.

The surgical plan should begin with identifying the anatomical problem(s) and then proceeding to the design of a stepwise surgical plan that addresses each issue.

## Dog Bites

Dog-bite injuries occur at a rate of more than 750,000 incidences per year in the US resulting in significant morbidity, with 4%–8% of these injuries resulting in periocular trauma.<sup>5,31–35</sup> Children are at particular risk and demonstrate a disproportionately higher incidence of dog-related eyelid trauma compared with adults. It has been estimated that the likelihood of a child sustaining a dog bite in their lifetime is around 50%, and approximately 80% of severe dog bites in children involve the head and neck.<sup>5,31–35</sup>

When evaluating patients who have suffered dog-related injuries, it is critical to ascertain information regarding the dog's health and rabies vaccination status. In the majority of dog-related trauma cases, the dog is known to the victim. If rabies is suspected, the local health department should be notified and rabies prophylaxis should be strongly considered because rabies infection can result in devastating sequelae.

Although globe injuries are uncommon in dog-related trauma,<sup>31–33</sup> a full and complete ophthalmic examination should be performed. Dog-related injuries do commonly result in canalicular injury, and the lacrimal system should be thoroughly evaluated in all cases.<sup>35</sup>

The repair of dog bite injuries follows the general principles of the techniques described earlier: The priority is to recreate normal function through re-establishing normal anatomical architecture. The secondary goal is to optimize cosmesis. As contamination is a common occurrence, copious irrigation with antibiotic irrigant is required. Antibiotic prophylaxis has been controversial, but because injuries are known to harbor a high rate of microbial contamination, we recommend prophylaxis with broad-spectrum antibiotics. *Pasteurella multocida* is the most common isolate in dog bite injuries, but a number of pathogens have been described in these instances, and surgeons should maintain a low threshold for obtaining culture and adjusting antibiotic coverage when indicated.<sup>8,11</sup>

## Lacrimal Injury

Medial upper and lower eyelid injuries often can result in trauma to the lacrimal system. Indeed, 16% of all eyelid lacerations from either penetrating or blunt trauma result in canalicular injury.<sup>3,4</sup> Lacerations that involve tissue medial to the punctum should be treated as canalicular involving until proven otherwise. Testing at the bedside with lacrimal irrigation or canalicular probing is possible, but we advocate testing the integrity of the lacrimal system in a controlled environment, such as in the operating room, when possible. We also advocate for the repair of all canalicular injuries, including monocanicular injuries with temporary stenting. There has been some controversy regarding this topic in the literature because some canalicular lacerations that are not repaired do not result in epiphora.<sup>3,4,36</sup> Because there is no predictive test to separate those injuries that will result in epiphora from those that will not, we defer to the wisdom of Hawes and Dortzbach, who state, “The only way to avoid symptomatic patients is to repair all canalicular lacerations.”<sup>37</sup>

The surgical steps of canalicular injury repair follow the general principles of those outlined earlier: The primary goal is to recreate the normal functioning anatomy with a secondary goal of optimizing cosmesis. We recommend copious but gentle cleaning of the lacerated tissues with antibiotic irrigant followed by gentle exploration of the medial tissues to identify the distal cut end of the canaliculus. Once the distal cut end is identified, we advocate placement of either a monocanicular or bicanicular stenting system to remain in place for approximately 4 weeks.

When difficulty arises in identifying the distal cut end, irrigation of the intact limb of the system with fluorescein dyed saline or viscoelastic can be used for identification. With patience, the distal cut end should be possible to identify in most cases.

A recent analysis of outcomes following repair of canalicular injury by Murchison and Bilyk revealed that repair of canalicular lacerations is more successful when performed in the operating room under general anesthesia under the direct supervision of an experienced oculoplastic surgeon. The authors found no significant difference in success between monocanicular and bicanicular stenting systems when controlling for other variables.<sup>4</sup>

Multiple studies have reinforced the fact that canalicular lacerations can be repaired several days after the initial injury without compromising the

success of the surgery, but we advocate for repair of these injuries as early as possible.<sup>4,37,38</sup> Our experience is that after 24–48 hours, an increased degree of difficulty exists in finding the distal cut end of the canaliculus.

In cases where the lacrimal system cannot be repaired, further lacrimal surgery, such as dacryocystorhinostomy, or more commonly conjunctivodacryocystorhinostomy can be explored, but these interventions should be deferred until full healing of the lacerated tissues has taken place.

## Eyelid Burns

Whether via thermal or chemical injury, burns can have devastating effects that can result in considerable ophthalmic morbidity. Severe burn injuries frequently involve the face, with the incidence of eyelid involvement being 20%–30%.<sup>39</sup> Fortunately, the presence of the eyelids, blink reflexes, Bell's phenomenon, and shielding of the eyes with arms and hands often prevent ocular surface injury.<sup>40–42</sup>

In the acute phase, attention is directed to protecting the globe and ocular surface from exposure and desiccation. Frequent lubrication is nearly universally required. Other measures such as moisture chambers and temporary tarsorrhaphy are commonly employed in these cases.<sup>40–42</sup>

In the majority of cases, first-degree burns behave similarly to eyelid abrasions and superficial lacerations and may be treated as such. Many of these injuries heal well by second intention. Frequent ocular surface lubrication and lubrication of the skin with moist gauze and ophthalmic ointment can aid in the re-epithelization of these injuries.<sup>40–42</sup>

Second- and third-degree burns typically demonstrate considerable tissue destruction and can develop early eyelid retraction or cicatricial ectropion. In these injuries, emergent temporizing measures such as suture tarsorrhaphy placement may be required to protect the ocular surface. Early surgical intervention is indicated in cases of ocular surface decompensation. Fortunately, permanent visual impairment is rare in cases where appropriate early surgical intervention is employed.<sup>40–42</sup>

When the cicatricial phase of healing is complete, burn injuries can be treated using the principles outlined earlier. In most cases, the anterior lamella requires the majority of the reconstructive effort. Eyelid retraction and/or ptosis may also require intervention. In severe cases, mucous membrane grafting may be required to restore the posterior lamella to avoid a keratinized surface contacting the ocular surface.<sup>43</sup>

## CONCLUSIONS

Periorbital injury and eyelid trauma demonstrate a wide spectrum of presentations from superficial abrasions to globe-threatening injury. The evaluation of these patients requires stepwise and methodical examination with a focus on anatomical architecture of the periorbital structures. When injuries are identified, the treatment plan should be developed thoughtfully, with an emphasis on first identifying the anatomical problems and then devising solutions. The primary goal of reconstruction is preservation of vision and protection of the globe. To achieve this goal, one must recreate the injured anatomy with a focus on the functional subunits. Secondly, the surgeon must consider the long-term cosmesis of the patient. Fortunately, achieving this secondary goal often follows from the restoration of normal functional anatomy.

Orbital Diseases

Jonathan J. Dutton

12.10

**Definition:** The orbit is the bony cavity that contains the eye, eye muscles, lacrimal gland, and neural and vascular structures that serve eye function. Numerous diseases involving any of these structures occur in the orbit and can affect visual function.

Key Features

- A mass lesion of the orbit may cause proptosis or displacement of the eye.
- Orbital lesions may be the presenting sign of systemic diseases such as metastatic cancer.
- Demographics such as age, sex, time course of presentation, and location within the orbit may be helpful in making a specific diagnosis.
- Treatment of orbital lesions may be medical, such as the use of corticosteroids or radiotherapy for inflammatory disease, and does not always require surgery.

INTRODUCTION

The orbit and ocular adnexa are important sites for primary and secondary diseases. Various tissue types, such as osseous, vascular, neural, muscular, fibrous, adipose, and glandular, may be involved with specific pathologies.<sup>1–5</sup> Tumors or inflammations can secondarily invade the orbit from periorbital regions including the paranasal sinuses, eyelids, and intracranial compartment.

CLINICAL EVALUATION

The initial step in the evaluation of orbital disease is a complete ophthalmic examination.<sup>5</sup> A careful medical and ophthalmic history, including time course of the disease, past trauma, ocular surgery, and systemic illnesses, must be obtained. A complete clinical examination includes assessment of visual acuity and visual fields, anterior and posterior segment evaluation, optic nerve function, and external and periorbital inspection. The use of modern imaging techniques is almost always indicated—the choice depends on the disease processes suspected.

In this chapter, the most common orbital lesions are categorized by diagnostic criteria to enable the reader to evaluate patients more easily and establish a meaningful differential diagnosis (Tables 12.10.1–12.10.3).<sup>5,6</sup> In addition, the key points and diagnostic criteria for each lesion are given.

METASTATIC TUMORS

INTRODUCTION

Metastatic tumors represent 2%–3% of all orbital tumors.<sup>6</sup> In 30%–60% of patients, orbital metastases develop before the diagnosis of the primary tumor (Table 12.10.4). Metastases reach the orbit via hematogenous spread and occur less commonly than do uveal metastases. In adults, metastases are usually carcinomas. In children, metastases are more likely to be sarcomas and embryonal tumors of neural origin. Only 4% of orbital metastases are bilateral. Clinical symptoms include proptosis, axial displacement of the globe, ptosis, diplopia, pain, and chemosis<sup>7</sup> (Fig. 12.10.1).

METASTATIC CARCINOMA

Key Points

The most common primary sites of metastatic carcinoma to the orbit are the breast, lung, prostate, gastrointestinal tract, and kidney.<sup>8–10</sup> Key features are:

- For breast carcinoma, the interval from primary diagnosis to orbital metastasis is 3–5 years.

**TABLE 12.10.4** Primary Origins of Metastatic Tumors of the Orbit

Origin	Percent
Breast	53
Prostate	11
Gastrointestinal	11
Lung	4
Sarcomas and other	21

Modified from Rootman JL. Diseases of the orbit. A multidisciplinary approach. Philadelphia, PA: JB Lippincott; 1988. p. 119–39; and Shields JA, editor. Diagnosis and management of orbital tumors. Philadelphia, PA: WB Saunders; 1989. p. 291–315.

- In scirrhous cell breast carcinoma and gastric carcinoma, enophthalmos may result from orbital fibrosis.
- Metastatic lung cancer is seen most commonly in males aged 45–60 years who smoke and may present before the primary is discovered.
- Prostatic metastases occur most commonly in elderly men, and pain is common because of bony involvement.
- Metastases are characterized by a rapid onset of orbital symptoms, which include exophthalmos and globe displacement.

## Orbital Imaging

Metastatic carcinomas usually are poorly defined, nonencapsulated, diffuse masses that are somewhat infiltrative (Fig. 12.10.2). Extraocular muscles are often involved. Osteoblastic changes may be seen with prostatic carcinoma. On magnetic resonance imaging (MRI), the T1-weighted image is usually isointense and the T2-weighted image hyperintense to muscle.

## Treatment and Prognosis

Treatment requires chemotherapy combined with local radiotherapy. Orchiectomy may be indicated for prostate carcinoma and hormonal therapy for breast carcinoma.

Orbital metastases from carcinoma reflect more widespread systemic disease, so the prognosis for survival is generally poor.

**Fig. 12.10.2** CT Scan of a Metastatic Breast Carcinoma With an Irregular Mass in the Right Retrobulbar Orbit.

### BOX 12.10.1 Causes of Abaxial Globe Displacement

#### Downward Displacement

- Fibrous dysplasia
- Frontal mucocele
- Lymphoma
- Neuroblastoma
- Neurofibroma
- Schwannoma
- Subperiosteal hematoma
- Thyroid orbitopathy

#### Upward Displacement

- Lacrimal sac tumors
- Lymphoma
- Maxillary sinus tumor
- Metastatic tumors

#### Lateral Displacement

- Ethmoid mucocele
- Lacrimal sac tumors
- Lethal midline granuloma
- Metastatic tumors
- Nasopharyngeal tumors
- Rhabdomyosarcoma

#### Medial Displacement

- Lacrimal fossa tumors
- Sphenoid wing meningioma

The direction of ocular displacement may be helpful in narrowing the differential diagnosis.

## LACRIMAL GLAND LESIONS

### INTRODUCTION

Lesions of the lacrimal gland include infiltrative processes such as inflammatory diseases and lymphoma,<sup>11</sup> structural disorders (such as cysts), and epithelial neoplasms.<sup>12–16</sup> Epithelial tumors represent 20%–25% of all lacrimal gland lesions. The appropriate management of lacrimal fossa lesions requires a thorough evaluation and determination of the cause. Almost all lacrimal gland lesions result in a mass effect, with swelling of the lateral eyelid and often with a downward and medial displacement of the globe (Box 12.10.1). Inflammatory processes are more commonly associated with pain, eyelid edema, and conjunctival chemosis and injection.

## PLEOMORPHIC ADENOMA (BENIGN MIXED CELL TUMOR)

### Key Points

Pleomorphic adenomas occur mainly in the orbital lobe and rarely in the palpebral lobe of the lacrimal gland.<sup>17–20</sup> They are composed of epithelial and mesenchymal elements (thus the term benign “mixed” cell tumor), but both elements are derived from epithelium. Key features are:

- They represent 3%–5% of all orbital tumors, 25% of lacrimal mass lesions, and 50% of epithelial lacrimal gland tumors.
- They occur most commonly in the second to fifth decades of life (mean age, 39 years).
- The male to female ratio is 1.5:1.

Orbital symptoms are painless proptosis, downward displacement of the globe, diplopia, retinal striae, fullness of the upper eyelid, and a palpable eyelid mass. These tumors are slowly progressive over 12 or more months.

### Orbital Imaging

Well-circumscribed, round-to-oval, encapsulated lesions are typical. Remodeling of the bone may be seen with long-standing tumors, but no bone destruction occurs. The tumors may be cystic and may contain areas of calcification. On MRI the T1-weighted image is hypointense and the T2-weighted image hyperintense to muscle.

### Pathology

Pleomorphic adenomas are encapsulated tumors that demonstrate ducts, cords, and squamous pearls, with myxoid and chondroid tissue (Fig. 12.10.3).

**Fig. 12.10.3 Benign Mixed Tumor.** (A) The patient had proptosis of the left eye for quite some time. It had gradually increased in severity. (B) The characteristic diphasic pattern is shown. It consists of a pale background that has a myxomatous stroma and a relatively amorphous appearance, contiguous with quite cellular areas that contain mainly epithelial cells. C, Cellular epithelial areas; M, myxomatous stroma; S, surface of tumor. (Reproduced with permission from Yanoff M, Fine BS. Ocular pathology. 5th ed. St Louis, MO: Mosby; 2002.)

### Treatment and Prognosis

These adenomas must be excised completely with an intact capsule; biopsy or incomplete removal may result in recurrence associated with infiltration. Malignant degeneration occurs at a rate of 10% in 10 years.

The prognosis generally is very good despite the small possibility of malignant transformation.

## ADENOID CYSTIC CARCINOMA

### Key Points

Adenoid cystic carcinoma accounts for 23% of all epithelial tumors of the lacrimal gland and is the most common epithelial malignancy of the lacrimal gland (Table 12.10.5).<sup>21</sup> Key features are:

- It occurs most commonly in the fourth decade of life but may be seen at any age.
- It is slightly more common in women.
- The duration of symptoms is generally short—often less than 6 months, and usually less than 12 months.

Orbital symptoms include proptosis, downward globe displacement, ptosis, and diplopia. Orbital pain as a result of perineural spread is common, seen in 10%–40% of cases.

### Orbital Imaging

Computed tomography (CT) and MRI usually show a poorly demarcated, irregular lesion that may extend along the lateral wall to the orbital apex. Bone destruction is common, and foci of calcification are seen frequently. On MRI the T1- and T2-weighted images are hyperintense to muscle, and the signal is heterogeneous.

### Pathology

Solid cords of malignant epithelial cells are seen, with cystic spaces (“Swiss cheese” appearance) or hyalinization of cylinders of connective tissue (Fig. 12.10.4).

### Treatment and Prognosis

Treatment consists of radical en bloc excision or exenteration, with wide margins including bone. A recent histological study<sup>22</sup> showed that 80% of these lesions involved adjacent bone. Adjunctive radiotherapy for incompletely excised lesions may be necessary. The prognosis is often poor, with relentless recurrences. The mortality rate is high.

## MESENCHYMAL TUMORS

### INTRODUCTION

Nonosseous mesenchymal tumors arise from fibroblasts, myoblasts, and lipoblasts. Classification of such lesions is difficult, as their features overlap, so the terminology is confusing. Together these orbital lesions form an important group that accounts for about 8% of all orbital lesions.<sup>23–33</sup>

**TABLE 12.10.5 Frequency of Lacrimal Fossa Lesions**

Lesion	Frequency (%)
Dacryoadenitis	51
Pleomorphic adenoma	18
Reactive lymphoid hyperplasia	9

Pleomorphic adenocarcinoma	2
Plasmacytoid lesions	1

Modified from Rootman JL. Diseases of the orbit. A multidisciplinary approach. Philadelphia, PA: JB Lippincott; 1988. p. 119–39; and Shields JA, editor. Diagnosis and management of orbital tumors. Philadelphia, PA: WB Saunders; 1989. p. 291–315.

**Fig. 12.10.4 Adenoid Cystic Carcinoma.** (A) The patient had a rapidly progressing proptosis of the left eye. (B) The characteristic “Swiss cheese” pattern (S) of adenoid cystic carcinoma is shown. The “Swiss cheese” tumor is also present in the perineural sheath around the ciliary nerve (C). Adenoid cystic carcinoma is noted for its rapid invasion of ciliary nerves. (Reproduced with permission from Yanoff M, Fine BS. *Ocular pathology*. 5th ed. St Louis, MO: Mosby; 2002.)

## FIBROUS HISTIOCYTOMA

### Key Points

Fibrous histiocytoma is a benign or malignant mesenchymal tumor that arises from fascia, muscle, or other soft tissues.<sup>34,35</sup> In children, it may result from early orbital radiotherapy. In adults, it is the most common mesenchymal orbital tumor, usually seen in middle-aged patients (40–60 years).

The upper nasal quadrant is the most common orbital site. Symptoms are proptosis, decreased vision, ptosis, motility restriction, and epiphora. The lesions may be circumscribed or infiltrative and can be locally aggressive.

### Orbital Imaging

Usually a well-defined, rounded mass is seen, as in other benign lesions, but the tumor can be more infiltrative. On MRI the signal is heterogeneous, with isointense T1 and variable T2 signals with respect to muscle. Enhancement with gadolinium is moderate.

### Pathology

The tumor is a mixture of spindle-shaped fibroblasts and histiocytes arranged in a storiform pattern twisted about a central focus (Fig. 12.10.5). The benign form (63% incidence) is a well-circumscribed, slow-growing lesion with a fine capsule. A small potential exists for malignant degeneration.

The malignant form (37% incidence) is more infiltrative and rapidly growing and is often associated with pain and necrosis.

### Treatment and Prognosis

Local surgical excision for benign or orbital exenteration for malignant lesions is required, with recurrences being common (in up to 30% of

**Fig. 12.10.5 Fibrous Histiocytoma.** (A) This is the fourth recurrence of an orbital tumor that was first excised 10 years previously. The histology of the primary lesion and of the four recurrences appear identical. (B) A histological section shows the diphasic pattern consisting of a histiocytic component (H), mainly on the far left, and a fibrous component (F). (Reproduced with permission from Yanoff M, Fine BS. *Ocular pathology*. 5th ed. St Louis, MO: Mosby; 2002.)

cases). Radiotherapy offers no benefit, and the effects of chemotherapy are unknown.

For the benign form, the prognosis for life is excellent. With malignant tumors, the overall mortality rate is more than 40%.

## RHABDOMYOSARCOMA

### Key Points

Rhabdomyosarcoma is the most common soft tissue mesenchymal tumor in children, accounting for 3.4% of all childhood malignancies.<sup>36–38</sup> The tumors arise from pluripotential mesenchymal precursors that normally differentiate into striated muscle cells. About 70% occur during the first decade of life (mean age, 7–8 years; range, 0–78 years), and boys are affected more commonly than girls at a ratio of 5:3. In the orbit, the most common histological variant is the embryonal type, followed by the alveolar type.

Symptoms may be acute to subacute, with rapidly progressive proptosis, eyelid edema, and ptosis. This rapidity may cause diagnostic confusion with an infectious process. The tumor is located in the retrobulbar muscle cone in 50% of cases, and in the superior orbit in 25% of cases.

### Orbital Imaging

Typically, the tumor presents as an irregular but well-defined soft tissue mass (Fig. 12.10.6). Bony erosion may be seen but is uncommon. On MRI the T1 signal is isointense to hyperintense, and the T2 signal is hyperintense with respect to muscle.

### Pathology

Cross-striations may be seen in 50%–60% of embryonal-type tumors and in 30% of the alveolar type (Fig. 12.10.7). Myoglobulin is a specific

Fig. 12.10.6 Rhabdomyosarcoma of the Lateral Orbital Wall in a 7-Year-Old Girl.

TABLE 12.10.6 Frequency of the Most Common Neurogenic Orbital Lesions

Lesion	Frequency (%)
Sphenoid wing meningioma	30
Optic nerve glioma	22
Neurofibroma	19
Schwannoma	14

Other	4

Data from Rootman JL. Diseases of the orbit. A multidisciplinary approach. Philadelphia, PA: JB Lippincott; 1988. p. 119–39; Shields JA, editor. Diagnosis and management of orbital tumors. Philadelphia, PA: WB Saunders; 1989. p. 291–315; and the author’s personal data.

immunohistochemical marker. Electron microscopy shows actin myofilaments and myosin filaments.

Staging

There are four stages:

- Localized tumor, completely resected.
- Regional spread, ± positive nodes, grossly resected.
- Gross residual tumor remaining after incomplete resection.
- Distant metastases.

Treatment and Prognosis

An immediate biopsy is required to confirm the diagnosis. Surgical excision is carried out only if the lesion is well circumscribed and the excision can be performed easily without excessive tissue damage. Local radiotherapy doses are 4000 cGy for stage II and 5000 cGy for stages III and IV. Adjuvant chemotherapy is given using vincristine, actinomycin D, and cyclophosphamide. Some centers prefer only surgery and chemotherapy to avoid the potential for radiation-induced orbital malignancies in children.<sup>39</sup>

The 5-year survival rate is 90%–95%. A more favorable prognosis exists for orbital tumors because of the near absence of orbital lymphatics. For local treatment failures, orbital exenteration may be necessary.

NEUROGENIC TUMORS

INTRODUCTION

Peripheral nerves in the orbit are subject to tumors that arise from various cellular components, such as Schwann cells, axons, endoneural fibroblasts, and nerve sheaths (Table 12.10.6). In contrast, the optic nerve, which represents a white-matter tract of the central nervous system (CNS), may give rise to CNS tumors such as astrocytomas and meningiomas.

Fig. 12.10.7 Embryonal Rhabdomyosarcoma. (A) The patient has a unilateral right ocular proptosis of very recent onset. Often, rhabdomyosarcoma presents rapidly, causes lid redness, and is mistaken for orbital inflammation. (B) A marked embryonic cellular pattern is shown, hence the term embryonal rhabdomyosarcoma (A, relatively acellular area; B, blood vessels; C, relatively cellular area). (C) A trichrome stain shows characteristic cross-striations in the cytoplasm of some of the rhabdomyoblasts. Cross-striations (C), although not abundant in embryonal rhabdomyosarcoma, can be seen in sections stained with hematoxylin and eosin but are easier to see with special stains. (Reproduced with permission from Yanoff M, Fine BS. Ocular pathology. 5th ed. St Louis, MO: Mosby; 2002.)

PLEXIFORM NEUROFIBROMA

Key Points

Plexiform neurofibroma is the most common benign peripheral nerve tumor in the eyelid and orbit and is considered characteristic of neurofibromatosis.<sup>40–43</sup> The tumor grows along the nerve, is invasive, and is not encapsulated. Key features are:

- A propensity for sensory nerves, but may also involve motor, parasympathetic, and sympathetic nerves.
- Children in the first decade of life are affected most commonly.
- 31% of plexiform neurofibromas occur in the eyelids.

**Fig. 12.10.8 Plexiform Neurofibroma of the Right Eyelid in a Child With Neurofibromatosis.**

**Fig. 12.10.9 Plexiform Neurofibroma.** Diffuse proliferation of Schwann cells within the nerve sheath enlarges the nerve. *N*, Thickened abnormal nerves.

Clinically, this tumor has been described as a palpable “bag of worms,” with thickened overlying skin and an S-shaped eyelid (Fig. 12.10.8).

It may be associated with uveal neurofibromas (50%), iris (Lisch) nodules (77%), prominent corneal nerves (25%), optic nerve gliomas (15%), and pulsatile proptosis from an absence of the greater sphenoid wing.

## Orbital Imaging

A diffuse, irregular mass is seen with variable contrast enhancement. It may involve extraocular muscles, orbital fat, and the cavernous sinus. On MRI the T1 is hypointense and the T2 hyperintense to muscle.

## Pathology

Interwoven bundles of axons, Schwann cells, and endoneurial fibroblasts are seen in a mucoid matrix (Fig. 12.10.9). A characteristic cellular perineural sheath defines the tumor cords. Immunohistochemistry is positive for S100.

## Treatment and Prognosis

Surgical excision is generally difficult and frustrating, with excessive bleeding and a poor cosmetic result. Repeated debulking may be necessary for severe symptoms, and orbital exenteration for extensive cases. Radiotherapy offers no benefit.

There is a small risk of malignant transformation. These tumors may occasionally erode into the anterior cranial fossa, which results in death.

## SCHWANNOMA (NEURILEMMOMA)

### Key Points

Schwannoma is a Schwann cell tumor of neural-crest origin that arises as an outpouching from peripheral or cranial nerves (e.g., acoustic neuroma).<sup>44</sup> Schwannomas represent 1% of all orbital tumors and 35% of peripheral nerve tumors. They are mostly benign but rarely may undergo malignant transformation in patients with neurofibromatosis.

Schwannoma is seen most commonly in young adults to middle-aged individuals (20–50 years). It presents as a slow-growing, painless,

**Fig. 12.10.10 Neurilemmoma.** (A) Proptosis of the patient's left eye had been present for many months and was increasing in size. An orbital tumor was removed. (B) Ribbons of spindle Schwann cell nuclei can be seen. This shows a tendency toward palisading. Areas of relative acellularity, mimicking tactile corpuscles, are called Verocay bodies. This pattern is called the Antoni type A pattern. (Reproduced with permission from Yanoff M, Fine BS. Ocular pathology. 5th ed. St Louis, MO: Mosby; 2002.)

well-defined solitary mass, usually in the superior orbit, and is frequently cystic. Orbital symptoms may include exophthalmos, diplopia, and visual loss from optic nerve compression.

## Orbital Imaging

The tumor is typically an extraconal, fusiform, well-defined, sometimes cystic mass that is aligned anteroposteriorly along the involved nerve. On MRI the signal is homogeneous to heterogeneous; T1 is hypointense and T2 isointense to muscle.

## Pathology

The encapsulated mass has yellow areas and patterns of cells described as Antoni A (whorls) or Antoni B (no palisading) patterns (Fig. 12.10.10). Spindle cells are seen with vesiculated nuclei in a palisading configuration. The cells are negative for alcian blue and positive for S100.

## Treatment and Prognosis

Surgical excision is required. The prognosis for life is good, except following intracranial spread. Late orbital recurrences may be seen after partial excision.

## MALIGNANT PERIPHERAL NERVE SHEATH TUMOR (MALIGNANT SCHWANNOMA)

### Key Points

Malignant peripheral nerve sheath tumors are rare malignant tumors of Schwann cells and perineural cells that arise de novo or in association with neurofibromatosis.<sup>45,46</sup> When associated with neurofibromatosis, the onset is slow and characterized by proptosis, globe displacement, and occasionally pain, ptosis, visual loss, diplopia, and chemosis. The tumors generally occur in patients 20–50 years of age, or earlier in neurofibromatosis.

The clinical course is characterized by relentless invasion along tissue planes to the middle cranial fossa. Metastases to the lungs are common.

## Orbital Imaging

A poorly defined, irregular mass is seen. Bone destruction may occur when the lesion is large.

## Pathology

The tumor has plexiform, swollen nerve bundles and spindle-shaped cells in whorls of interlacing fascicles.

## Treatment and Prognosis

Wide surgical resection is required. Ancillary chemotherapy and radiotherapy may be palliative only. Prognosis is very poor, with death from metastases or intracranial spread.

## NEUROBLASTOMA

### Key Points

Neuroblastoma is an undifferentiated malignant tumor of primitive neuroblasts, which may be metastatic to the orbit.<sup>47</sup> It represents the second most common malignant orbital tumor in children after rhabdomyosarcoma. It arises from the sympathetic system and ganglia and represents the peripheral nervous system counterpart of retinoblastoma. Rarely, neuroblastomas may be primary lesions in the orbit, where they may arise from the ciliary ganglion. Key features are:

- 60% of the primary tumors occur in the abdomen.
- 10%–40% of systemic neuroblastomas result in orbital metastases, on average 3 months after diagnosis of the primary.
- 90% of orbital lesions originate from the abdomen.
- Only 8% of cases first present with an orbital lesion; in 92% of cases the presence of an extraorbital primary tumor is already known.
- 40% of orbital lesions are bilateral.
- The mean age at presentation is 2 years old.
- 75% of cases occur before the age of 4 years.

Symptoms include rapid progression of proptosis over several weeks, lid ecchymosis from necrosis and hemorrhage, eyelid edema, ptosis, Horner's syndrome (from mediastinal tumors), papilledema, retinal striae, and decreased vision. Systemic symptoms may involve fever, weakness, and an abdominal or thoracic mass.

## Orbital Imaging

An irregular, poorly circumscribed mass is seen, frequently associated with bone destruction and separation of sutures, especially at the zygoma. Metastases to the skull bones occur in 74% of cases.

## Pathology

The lesion is a soft, friable, bluish mass; small round cells that resemble lymphocytes with specks of calcium and areas of necrosis are seen. Electron microscopy reveals neurosecretory tubules.

## Treatment and Prognosis

If no systemic primary disease exists, the orbital tumor can be excised. With systemic primary disease, chemotherapy yields resolution in 60%–70% of cases in 4–6 months. Radiotherapy (1500 cGy in children and 4000 cGy in patients older than 10 years) may be used for local orbital disease.

Recurrences may be seen in 90% of cases over 1–2 years, and a 50%–60% mortality rate occurs after 2 years. Bony and orbital metastases are associated with a poorer prognosis.

## OPTIC NERVE GLIOMA (PILOCYTIC ASTROCYTOMA OF CHILDHOOD)

### Key Points

Optic nerve glioma is a neoplasm of astrocytes<sup>48</sup> that affects primarily children (mean age, 8 years). No sex predilection exists. The optic nerve alone is affected in 28% of cases; 72% involve the optic chiasm, and of these, 43% involve the chiasm and midbrain. In 29% there is an association

**Fig. 12.10.11** Optic Nerve Glioma in a Child With Neurofibromatosis Type 1.

**Fig. 12.10.12** Optic Nerve “Glioma.” Well-differentiated astrocytes spread out the pial septa (P). (Reproduced with permission from Yanoff M, Fine BS. Ocular pathology. 5th ed. St Louis, MO: Mosby; 2002.)

with type 1 neurofibromatosis. In neurofibromatosis, the lesion may be bilateral.

Symptoms include slow loss of vision, optic atrophy or edema, and proptosis. After an initial decrease, vision remains stable in 80% of patients. Hypothalamic signs may be seen in 22% of cases. Rapid enlargement of the lesion occurs from mucoid degeneration and arachnoid hyperplasia.

## Orbital Imaging

Typically the lesion appears as an intraconal, fusiform enlargement of the optic nerve with or without a chiasmal mass. The nerve may appear kinked with cystic spaces. On MRI the T1 signal is hypotense to isointense, and the T2 signal shows variable intensity compared with muscle (Fig. 12.10.11). Enhancement with gadolinium is variable.

## Pathology

Optic nerve gliomas demonstrate cystic spaces that contain a mucoid material and pial septae that are separated by well-differentiated astrocytes (Fig. 12.10.12). Eosinophilic Rosenthal fibers may represent degenerated astrocytic processes. Immunohistochemistry is positive for neuron-specific enolase.

## Treatment and Prognosis

Treatment consists of observation if the vision is good. The patient should be followed with serial MRI scans. Surgical excision is offered if a tumor approaches the chiasm. Surgery also is indicated for pain or disfiguring proptosis. The role of radiotherapy remains controversial; it may be associated with CNS complications. More recently, chemotherapy has shown promising results.<sup>49</sup>

Prognosis for vision is poor. For lesions confined initially to the optic nerve, prognosis for life is good. For those lesions that involve the chiasm, mortality approaches 20%. Once the midbrain and hypothalamus are involved, the overall prognosis is poor, with mortality exceeding 55%.

BOX 12.10.2 Calcified Orbital Lesions

- Phlebolith
- Orbital varix
- Lymphangioma
- Thrombosed atrioventricular shunt
- Chronic inflammation
- Malignant lacrimal gland tumors
- Optic nerve sheath meningioma
- Dermoid cyst
- Mucocele walls
- Fibro-osseous tumors

OPTIC NERVE SHEATH MENINGIOMA

Key Points

Optic nerve sheath meningioma is a benign neoplasm of meningothe-lial cells of arachnoid tissue<sup>50</sup> that affects primarily middle-aged adults (20–60 years). Women are involved slightly more commonly than men, at a ratio of 3:2. In 4%–9% of cases there is an association with type 1 neuro-fibromatosis, and in 6% of cases the lesion may be bilateral; 5% of menin-giomas are confined to the optic canal, which makes diagnosis difficult.

Symptoms and signs include slowly progressive proptosis over several years, visual loss, optic disc edema, optic atrophy, development of optico-ciliary shunt vessels, and ocular motility restriction.

Orbital Imaging

The lesion is usually seen as a tubular enlargement of the optic nerve with a characteristic “tram-track” pattern of an enhancing nerve sheath with a lucent central nerve. Small areas of calcification may be seen. Marked contrast enhancement on CT is characteristic. On MRI the T1 signal is hypointense, and the T2 signal is hyperintense. Heterogeneity results from low signal areas that represent calcium. Areas of subarachnoid fluid dis-tention are hyperintense.

Pathology

There are several histological types. The meningothe-lial type of lesion shows syncytial lobules of meningothe-lial cells. The psammomatous type demonstrates calcified concretions or psammoma bodies (Box 12.10.2). A rare angioblastic type contains vascular elements that resemble a hemangiopericytoma.

Treatment and Prognosis

Treatment consists of observation if the vision remains good. Surgical exci-sion is indicated in patients with blindness and significant proptosis or when the optic canal is threatened.<sup>51</sup> Radiotherapy may slow progression.<sup>52,53</sup> Prognosis for life is excellent, but visual outcome typically is poor.

LYMPHOPROLIFERATIVE DISEASES

INTRODUCTION

Lymphoid lesions are uncommon in the orbit and account for 6% of all orbital mass lesions (Table 12.10.7). This group includes lymphocytic, plas-macytic, and leukemic lesions. Among the lymphoid infiltrates, lesions are divided into three categories: idiopathic inflammations (pseudotumors), lymphoproliferative reactive and atypical diseases, and lymphomas. The relationships between the last two groups and their relationship to sys-temic disease are not always clear, and some confusion still surrounds the diagnosis and prognosis of each.

BENIGN REACTIVE LYMPHOID HYPERPLASIA

Key Points

This disease constitutes a benign proliferation of lymphoid follicles that contain polymorphic lymphocytes that are immunohistochemically poly-clonal.<sup>54,55</sup> Benign reactive lymphoid hyperplasia (BRLH) occurs most

TABLE 12.10.7 Frequency of Lymphoproliferative Diseases of the Orbit

Disease	Frequency (%)
Lymphoma	51
Reactive and atypical lymphoid hyperplasia	36
Plasma cell dyscrasias	7
Leukemia	2
Histiocytoses	4

Modified from Dutton JJ, Frazier Byrne S, Proia A. Diagnostic atlas of orbital diseases. Philadelphia, PA: WB Saunders; 2000. p. 1–5.

commonly in the anterior superior orbit, with a predilection for the lac-rimal gland (15%). The clinical course is indolent, with painless exoph-thalmos, globe displacement, and typically normal vision. A firm, rubbery mass is often palpable beneath the orbital rim, and there may be a pink subconjunctival “salmon-patch” infiltrate.

Orbital Imaging

An infiltrative mass is seen in the eyelids or anterior orbit. It typically molds to the globe and other adjacent structures and may extend along the rectus muscles. On MRI the T1 signal is hypointense and the T2 signal hyperintense to muscle.

Pathology

Typically, the tumor is a polymorphous array of small lymphocytes and plasma cells with mitotically active germinal centers (Fig. 12.10.13). Immu-nohistochemistry is positive for polyclonal T- and B-cell markers.

Treatment and Prognosis

Treatment involves systemic corticosteroids or local radiotherapy at 1500–2000 cGy. Some lesions may require cytotoxic agents (chlorambucil) for control. There is a 15%–25% chance of developing systemic lymphoma within 5 years.

ATYPICAL LYMPHOID HYPERPLASIA

Key Points

Atypical lymphoid hyperplasia (ALH) represents an intermediate between BRLH and malignant lymphoma and may be unilateral or bilateral. Pre-sentation is as for BRLH, but ALH may involve other systemic organs and more frequently does not respond to corticosteroids. There is a 15% inci-dence of extraorbital involvement. Systemic lymphoma may develop.

Orbital Imaging and Echography

CT and MRI scans are similar to those for BRLH.

Pathology

Monomorphous sheets of lymphocytes that have larger nuclei than those of BRLH are seen. Some abortive follicles may be present.

Treatment and Prognosis

If no systemic involvement exists, radiotherapy at 2500–3000 cGy is appro-priate. There is a 40% chance of systemic lymphoma developing within 5 years.

MALIGNANT ORBITAL LYMPHOMA (LYMPHOSARCOMA)

Key Points

Malignant orbital lymphoma is a low-grade malignancy characterized by a proliferation of monoclonal B cells (non-Hodgkin’s) that arise in lymph nodes or in an extranodal site such as the orbit.<sup>56–59</sup> Most commonly affected is the older age group (50–70 years). Clinically, a palpable mass

**Fig. 12.10.13 Reactive Lymphoid Hyperplasia.** (A) The patient noted a fullness of the lower right lid. Large, thickened, redundant folds of conjunctiva in the inferior cul-de-sac are seen. The characteristic “fish flesh” appearance of the lesion suggests the clinical differential diagnosis of a lymphoid or leukemic infiltrate or amyloidosis. (B) Lymphocytes are mature, quite small, and uniform; occasional plasma cells and large monocytoid lymphocytes. The uniformity of the lymphocytes makes it difficult to differentiate this benign lesion from a well-differentiated lymphosarcoma. The very mature appearance of the cells and the absence of atypical cells, along with the presence of plasma cells, suggests the diagnosis of a benign lesion. In such cases, testing using monoclonal antibodies may be quite helpful. If the population is of mixed B and T cells, the chances are that the tumor is benign. If it is predominantly of one cell type or the other, usually B cells, it is probably malignant and may represent mucosal-associated lymphoid tissue of the conjunctiva. (Reproduced with permission from Yanoff M, Fine BS. *Ocular pathology*. 5th ed. St Louis, MO: Mosby; 2002.)

may be present in the anterior orbit. Symptoms include exophthalmos, occasional diplopia, lid edema, and ptosis (Fig. 12.10.14).

In 75% of cases the process is unilateral, and in 25% it is bilateral; 40% of cases are associated with systemic disease at the time of diagnosis.

### Orbital Imaging

A well-defined mass is seen that molds to encompass adjacent structures. Most lesions are located in the anterior, superior, and lateral orbit and frequently involve the lacrimal gland (Fig. 12.10.15).

### Pathology

Infiltrative, anaplastic lymphocytes with large cleaved nuclei and frequent nucleoli are seen. Follicles are absent. Immunohistochemistry reveals a monoclonal proliferation of B cells.

### Treatment and Prognosis

If no systemic involvement occurs, observation is warranted for low-grade differentiated lesions. For less well-differentiated types, chemotherapy or radiotherapy at 2500–4000 cGy is recommended, with local control rates of 60%–100%.<sup>60</sup>

**Fig. 12.10.14 Subconjunctival Anterior Orbital Lymphoma.**

**Fig. 12.10.15 Lymphoma Infiltrating Along the Lateral Orbital Wall.**

When the disease is confined to the orbit, the visual prognosis is excellent, but the overall prognosis for life is variable. A 60% chance exists of developing systemic lymphoma within 5 years.

## HISTIOCYTIC TUMORS

### INTRODUCTION

Histiocytic tumors are rare proliferative disorders of histiocytes that range from solitary benign lesions to those that exhibit a more malignant course. A typical feature of all these lesions is the presence of Langerhans' cells, a type of histiocyte normally found in the epidermis.

### EOSINOPHILIC GRANULOMA (HISTIOCYTOSIS X)

#### Key Points

Eosinophilic granuloma is the most common and benign form of the histiocytosis X group. The disease affects primarily children and teenagers (from birth to 20 years of age). It consists of a unifocal, granulomatous proliferation in bone. Orbital involvement occurs in up to 20% of cases, most commonly in the superotemporal orbit.

Clinically, a rapid onset of axial displacement of the globe and painful superolateral swelling occur. Erythema and inflammatory signs are seen in the overlying skin.

### Orbital Imaging

Typically, an osteolytic lesion is seen near the superotemporal bony rim. Usually an irregular contour is noted, with marginal hyperostosis. Occasionally, the lesion may extend into the cranial fossa.

**Fig. 12.10.16 Eosinophilic Granuloma.** (A) A 4-year-old boy presented clinically with rapid onset of erythema and swelling over the lateral edge of the left orbit. Osteomyelitis versus rhabdomyosarcoma was diagnosed clinically; the area was explored surgically. (B) Histological section shows large histiocytes (abnormal Langerhans' cells) and numerous eosinophils characteristic of a solitary eosinophilic granuloma. ([A], Courtesy Dr D.B. Schaffer. [B] Courtesy Schaffer DB. In: Yanoff M, Fine BS. Ocular pathology. 5th ed. St Louis, MO: Mosby; 2002.)

## Pathology

This is a soft, friable, tan-yellow tumor with sheets of binuclear, atypical histiocytes, eosinophils, and giant cells (Fig. 12.10.16). Characteristic Langerhans' granules are seen in the cytoplasm.

## Treatment and Prognosis

Surgical curettage generally is curative, but radiotherapy at 900–1500 cGy also may be used. The prognosis is very good.

## INFLAMMATIONS AND INFECTIONS

Inflammatory diseases are common orbital lesions that may simulate neoplasms. They include a variety of acute and subacute idiopathic processes, chronic inflammations, and specific inflammations of uncertain etiology. Most notable among these lesions is thyroid eye disease, which accounts for more than half of all such cases. See Chapter 12.15 for a discussion of inflammatory and infectious disorders of the orbit.

**Fig. 12.10.17 Right Superomedial Superficial Orbital Dermoid Cyst in a Young Child.**

### BOX 12.10.3 Common Cystic Lesions of the Orbit

- Dermoid cysts
- Conjunctival cysts
- Sweat gland cysts
- Microphthalmos with cyst
- Lacrimal gland cysts
- Lymphangioma
- Schwannoma
- Infectious abscesses

## THYROID EYE DISEASE

Thyroid eye disease is an autoimmune disorder that affects the orbital muscles and fat.<sup>61,62</sup> This accounts for nearly half of all orbital diseases seen clinically. See Chapter 12.14 for a complete discussion of this disorder.

## CYSTIC LESIONS

### INTRODUCTION

Structural lesions of the orbit include choristomatous lesions such as dermoid cysts, which arise from errors in embryogenesis, and anatomical abnormalities such as mucocoeles, which result from local disease processes (Box 12.10.3).

## DERMOID CYST

### Key Points

A dermoid cyst is a developmental choristoma (tumor of tissue not normally found in area), lined with epithelium and filled with keratinized material.<sup>63,64</sup> The majority of such cysts are located in the eyelids and orbit (Fig. 12.10.17). These cysts represent 24% of all orbital and lid masses, 6%–8% of deep orbital masses, and 80% of cystic orbital lesions. Dermoid cysts may lie latent for many years before growth and may be located superficially in the eyelid and anterior orbit or deep in the orbit. If ruptured, sudden growth may occur because of a secondary granulomatous inflammatory reaction.

### Superficial Lesions

Superficial lesions arise from a sequestration of epithelium during embryogenesis along bony suture lines. They are present in early infancy, typically in the superotemporal or superonasal quadrants. Clinically, they present as a slowly enlarging, unilateral, painless, firm mass. They may be mobile or fixed to underlying structures and are free from overlying skin.

### Orbital Imaging

The round, well-defined lesions have an enhancing rim that may contain calcium and a lucent center. They may be associated with a well-corticated bone defect.

### Pathology

The cyst usually has a thin, fibrous capsule and a central lumen lined with keratinized stratified squamous epithelium. If derived from conjunctiva, the lining may be cuboidal with goblet cells. The cyst wall contains hair follicles and sweat and sebaceous glands. The cyst contains keratin debris, hair shafts, and oily material. About 38% of cysts are associated with chronic granulomatous inflammation.

### Treatment and Prognosis

Complete surgical excision in one piece is required. The prognosis is excellent, but recurrences with infiltration may follow incomplete excision or rupture of the capsule.

### Deep Lesions

Deep lesions are seen in both children and adults. They are associated with any bony suture in the orbit and may extend across bones into the frontal sinus, temporal fossa, or cranium.

Symptoms from the slow-growing mass include proptosis, occasionally motility restriction, and decreased vision. Spontaneous rupture produces marked orbital inflammation.

### Orbital Imaging

The well-defined lesion has an enhancing rim that may contain areas of calcification. The central lumen is nonenhancing and of variable density, depending on its contents; it may show a fluid-fat interface. A bone defect may be seen.

### Pathology

A smooth, thin rim of keratinized squamous epithelium, which may have goblet cells if derived from conjunctiva, lines the cyst. The cyst wall contains hair shafts, and sweat and sebaceous glands are characteristic.

### Treatment and Prognosis

Treatment consists of total excision without rupture of the capsule. The prognosis is excellent.

## MUCOCELE

### Key Points

Mucoceleles arise from a primary obstruction of a paranasal sinus following trauma, sinusitis, or, rarely, a tumor.<sup>65</sup> Frequently, they expand into the orbit by expansion of a bony wall. Mucoceleles consist of a cystic mass filled with mucus and may be bounded by an eggshell layer of bone (when they become infected, mucoceleles are referred to as pyoceles). The majority of mucoceleles (70%) occur in adults (aged 40–70 years), and the frontal and ethmoid sinuses are most commonly involved—rarely the sphenoid sinus.

Symptoms include headache, exophthalmos, and a palpable fluctuant mass in the medial or superomedial orbit.

### Orbital Imaging

An opacified frontal or ethmoid sinus, loss of ethmoid septae, and a bony dehiscence (Fig. 12.10.18) are observed. The cystic content shows variable density and is nonenhancing.

Fig. 12.10.18 Anterior Ethmoid Sinus Mucocele Eroding Into the Orbit.

### Pathology

The lining is composed of pseudostratified, ciliated columnar epithelium with goblet cells. The cyst content is mucoid with chronic inflammatory debris.

### Treatment and Prognosis

Treatment consists of surgical excision with restoration of sinus drainage. Obliteration of the sinus with fat or muscle may be necessary to treat recurrences.

The prognosis is very good, but there is a significant rate of recurrence.

## MICROPHTHALMOS WITH CYST

### Key Points

Microphthalmos is a severe malformation of the globe that may be associated with cyst formation.<sup>66</sup> The microphthalmic eye may be associated with colobomas of the globe where the overlying sclera is thinned and bulging. Less commonly, a cyst may originate from the optic nerve, where it usually communicates with the subarachnoid space. The disorder presents at birth with a variably small eye and reduced visual acuity and the cyst is typically located in the inferior orbit.

### Orbital Imaging

On CT scan the globe is small or severely deformed. The cyst appears as a dark, low-attenuating density, similar to cerebrospinal fluid (CSF). A thin rim of higher density tissue similar to sclera surrounds it. The bony orbit is often enlarged from remodeling. Following contrast administration there is no enhancement of the cyst or its enclosing wall. On MRI T1-weighted images the cyst produces a homogeneous low signal that varies from iso-intense to hypointense similar to vitreous or CSF. On the T2-weighted image the cyst contents are hyperintense, and there is no enhancement with gadolinium.

### Pathology

This entity has a small malformed eye with a cyst composed of connective tissue continuous with the sclera. The cyst is lined by disorganized retinal and/or glial tissue and may contain choroidal remnants. Retinal tissue may not be recognizable in all cases.

### Treatment and Prognosis

When cysts are small with minimal symptoms, specific therapy is not necessary. If the globe is disfigured and there is no proptosis, a scleral shell may be applied for cosmetic improvement. With significant proptosis or orbital pain, the cyst can be deflated with repeated needle aspiration. In some cases, better cosmesis will be obtained with enucleation. The prognosis for vision is poor, but with appropriate and timely management the prognosis for cosmesis can be quite good.

## VASCULAR NEOPLASTIC AND STRUCTURAL LESIONS

### INTRODUCTION

Neoplastic lesions that arise from the vascular system include both benign and malignant tumors (Table 12.10.8). Unlike nonneoplastic vascular lesions, which usually reflect the hemodynamic functions of the underlying vascular structures, neoplastic lesions typically manifest only a mass effect, occasionally modified by some hemodynamic characteristics. They may be well circumscribed or infiltrative.

### CAPILLARY HEMANGIOMA (HEMANGIOENDOTHELIOMA)

### Key Points

Capillary hemangioma is a congenital hamartoma of tightly packed capillaries that typically presents during the first 6 months of life.<sup>6,56,67</sup>

**Fig. 12.10.19** Capillary Hemangioma of the Lower Eyelid in a Young Child.

**TABLE 12.10.8** Frequency of the Most Common Vascular Orbital Lesions

Lesion	Frequency (%)
Cavernous hemangioma	50
Capillary hemangioma	18
Hemangiopericytoma	13
Lymphangioma	10
Orbital varices	5
Other	5

Modified from Shields JA, editor. Diagnosis and management of orbital tumors. Philadelphia, PA: WB Saunders; 1989. p. 291–315.

It is generally unilateral and usually visible on the surface, but it may lie deep in the orbit (**Fig. 12.10.19**). More common in the superonasal quadrant of the upper lid, capillary hemangioma appears as a fluctuant mass that may involve the overlying skin as a reddish lesion. Capillary hemangiomas show rapid growth over weeks to months, followed by slow spontaneous involution over months to years.

## Superficial Lesions

Also known as the “strawberry nevus,” capillary hemangioma is confined to the dermis. It may be single or multiple and is generally elevated. Symptoms include ptosis, sometimes associated with astigmatism and amblyopia.

### Treatment and Prognosis

Observation is warranted in most cases because involution usually occurs. Recently systemic propranolol for 8–12 months has been shown to achieve dramatic resolution for superficial lesions.<sup>68</sup> Intralesional corticosteroids, radiotherapy, and, more recently, topical corticosteroids also have been advocated.<sup>69</sup> Surgery is useful for small, circumscribed lesions, but for larger ones, this may result in cosmetic compromise.

The prognosis is good; 30% of cases involute by 3 years of age, 60% by 4 years of age, and 75% by 7 years of age. Large lesions may not completely disappear.

## Deep Lesions

Deep lesions occur most frequently in the lids or posterior to orbital septum and are more common in the superonasal quadrant.

Symptoms are proptosis, displacement of the globe, subtle pulsations as a result of high vascular flow, and increasing size with the Valsalva maneuver or crying. Secondary amblyopia may result from distortion of the globe. Large lesions may sequester platelets.

### Orbital Imaging

A well-defined to infiltrating intraconal or extraconal lesion is observed with moderate to intense enhancement. On MRI the signals are homogeneous

**Fig. 12.10.20** Capillary Hemangioma. The tumor is composed of blood vessels of predominantly capillary size. (From a presentation by Dr W.C. Frayer to the meeting of the Verhoeff Society, 1989.)

to heterogeneous, being hypointense on T1 and hyperintense on T2 images. Flow voids appear as hypointense regions. Moderate enhancement is seen with gadolinium.

### Pathology

A florid proliferation of capillary endothelial cells and small capillaries is seen, with few spaces (**Fig. 12.10.20**). Mitoses are common, but this is not a malignant tumor.

### Treatment and Prognosis

Treatment consists of observation because many lesions will involute, although few orbital lesions completely disappear. If the lesion is large or amblyopia is present, local radiotherapy (500 cGy) or corticosteroids (systemic or local) may be indicated. If the lesion is small and well defined, surgery may be attempted. Recently propranolol has been shown to cause significant involution for tumors in the proliferative phase.<sup>70</sup>

The prognosis is excellent for vision and for life.

## CAVERNOUS HEMANGIOMA

### Key Points

Cavernous hemangioma is a benign, noninfiltrative, slowly progressive tumor of large endothelial-lined channels.<sup>5,6</sup> Although it is congenital, it typically becomes symptomatic in adults (aged 20–40 years). Cavernous hemangioma is usually found in an intraconal location, more commonly in the temporal quadrant. Rarely, it may be intraosseous.

Symptoms relate to its mass effect, which produces proptosis and late motility restriction. When cavernous hemangiomas are very large, choroidal folds and decreased vision may result. The lesions may enlarge during pregnancy.

### Orbital Imaging

A well-defined, oval to round, typically intraconal mass is seen with minimal enhancement. With large, long-standing lesions, molding of bone and internal calcification may occur. On MRI the lesion is isointense on T1 and hyperintense on T2 with respect to muscle. Signal voids represent calcific phleboliths. Enhancement with gadolinium is moderate.

### Pathology

The encapsulated nodular mass consists of dilated, vascular spaces lined by flattened endothelial cells (**Fig. 12.10.21**). Septae may contain lymphocytes and smooth muscle cells.

### Treatment and Prognosis

Surgical excision is required if the lesion is symptomatic—typically, there is little or no bleeding. There is no role for radiotherapy. The prognosis is excellent for vision and life.

**Fig. 12.10.21 Cavernous Hemangioma.** (A) Clinical appearance of left exophthalmos. (B) MRI shows optic nerve stretched over tumor that “lights up” in the T2-weighted image, characteristic of a hemangioma. ([A] From a presentation by Dr W.C. Frayer to the meeting of the Verhoeff Society, 1989. [B] Reproduced with permission from Yanoff M, Fine BS. *Ocular pathology*. 5th ed. St Louis, MO: Mosby; 2002.)

## LYMPHANGIOMA

### Key Points

Lymphangioma is a rare vascular hamartoma of lymphatic channels that is hemodynamically isolated from the vascular system.<sup>71</sup> It occurs in children and teenagers but most frequently in the first decade of life. The size of the lesion fluctuates with posture and the Valsalva maneuver and with upper respiratory infections.

### Superficial Lesions

Superficial lesions occur in the conjunctiva or lid and are visible as cystic spaces with clear fluid; they may be partially filled with blood.

### Deep Lesions

Symptoms with deep lesions are proptosis and diplopia. Spontaneous hemorrhage may lead to sudden enlargement and orbital pain and possible visual loss with the formation of “chocolate cysts.”

### Orbital Imaging

The orbital lesion is seen as a low-density cystic, intra- and extraconal mass with variable enhancement. No vascular component is seen on angiography. On MRI the lesion is hypointense on T1; on T2 the signal is hyperintense but may be variable depending on the state of hemoglobin degeneration.

### Pathology

Lymphangiomas show infiltrative endothelium-lined channels with a sparse cellular framework and lymphocytes. Lymphatic follicles often are seen in the walls of the tumor. Red blood cells are not present unless a secondary hemorrhage has occurred.

## Treatment and Prognosis

Observation is justified in most cases. Surgery may be hazardous and lead to poor cosmetic results. If acute hemorrhage causes severe symptoms, the lymphangioma may be evacuated and partial resection or ligation attempted. Recurrences are common. The lesion shows limited radiosensitivity. The prognosis is variable. Amblyopia is common from globe compression and recurrent hemorrhage.

## ARTERIOVENOUS FISTULA

### Key Points

Arteriovenous fistulas can be traumatic (more common in males than females, age range 15–30 years) or spontaneous (more common in females than males, age range 30–60 years).<sup>5,6</sup> Symptoms depend on blood flow rate—most fistulas are associated with venous dilation, fluid transudation, sludging, and thrombosis.

### Low-Flow Type

Low-flow fistulas usually result from dural artery-to-cavernous sinus shunts. Symptoms are chemosis, increased episcleral venous pressure, and venous dilatation.

### High-Flow Type

High-flow fistulas usually result from carotid artery-to-cavernous sinus shunts. Symptoms are chemosis, orbital edema, proptosis, pulsatile exophthalmos, audible bruit, secondary glaucoma, retinal vascular dilation, papilledema, afferent pupillary defect, decreased vision, and cranial nerve palsies (third and sixth nerves most common).

### Primary Shunts

Primary shunts (mainly congenital malformations) are rare in the orbit and are usually associated with syndromes (e.g., Wyburn–Mason and Osler–Weber–Rendu).

### Secondary Shunts

Secondary shunts are located outside the orbit, usually in the cavernous sinus. Retrograde blood flow is directed forward into the orbital veins. Secondary shunts may be spontaneous (from venous thrombosis or hypertension) or secondary (from trauma). The latter are usually of the high-flow type, with 40%–50% causing visual loss.

### Orbital Imaging

A dilated superior ophthalmic vein with enlargement of the superior orbital fissure is seen; erosion of the anterior clinoid processes occurs.

## Treatment and Prognosis

Resolution of small, spontaneous low-flow shunts frequently occurs from thrombosis and is seen in up to 40% of cases. Embolization is not indicated unless visual loss, glaucoma, or severe pain is present. With traumatic, high-flow shunts, spontaneous resolution is less common. The rate of visual loss is 40%–50%, and intervention is therefore required. Balloon or other embolization is the treatment of choice.

With treatment, the prognosis is generally good for vision.

## VARICES

### Key Points

Orbital varices are dilated venous channels that represent one end of the spectrum of developmental venous anomalies that also includes lymphangiomas.<sup>72</sup> They are prone to spontaneous hemorrhage and thrombosis formation. Varices typically present with slowly progressive intermittent proptosis. Ophthalmoplegia and pain are variable depending on the size and location. Symptoms frequently are exacerbated by changes in head position, bending forward, or by Valsalva maneuver (Fig. 12.10.22).

**Fig. 12.10.22 Orbital Varix.** (A) Clinical appearance of a dilated anterior superomedial orbital varix during Valsalva. (B) Orbital computed tomography of a different patient showing a heterogeneous dilated venous channel in the posterior orbit with areas of enhancement and low-density regions representing thrombus.

**Fig. 12.10.23 Basal Cell Carcinoma.** (A) Patient with a basal cell carcinoma of the left upper eyelid and brow. (B) Computed tomography scan showing an irregular multilobulated medium density mass in the superolateral eyelid extending into to orbit.

## Orbital Imaging

On CT, dilated varices appear as serpiginous structures of increased density. The vascular channels can be seen to enlarge with Valsalva maneuver, even in patients without orbital symptoms. With contrast administration there is marked enhancement where the vascular channels are patent to blood flow. On MRI T1 images the varix produces a low isointense signal that typically shows marked enlargement in size with Valsalva. On T2 images flowing blood produces a dark signal void. With gadolinium, enhancement is marked, except in areas of thrombus formation where there is little or no enhancement.

## Pathology

A single large vessel may dominate an orbital varix or there may be multiple ectatic veins. The vessel walls may be fibrotic, and the lumens may be thrombosed or contain phleboliths resulting from calcification of old thrombus.

## Treatment and Prognosis

No treatment is required if symptoms are mild. For more severe orbital symptoms, surgical evacuation of clots and partial excision of ectatic venous channels may be necessary. Embolization with coils may limit traumatic dissection. The prognosis for vision is generally good. With very large lesions, visual loss can result from prolonged optic nerve compression.

## SECONDARY TUMORS

### INTRODUCTION

Secondary tumors of the orbit invade from adjacent structures and areas. They may spread from the globe by extending through the sclera or expand backward through the orbital septum from the conjunctiva or through the orbital walls from the paranasal sinuses or intracranial compartment.

### BASAL CELL CARCINOMA

#### Key Points

Basal cell carcinoma is the most common secondary tumor involving the orbit. It typically spreads backward from the eyelids or brow (Fig. 12.10.23). Lesions originating in the medial canthus are more likely to invade the orbit because of anatomical discontinuities in the orbital septal complex.<sup>73</sup> Most patients are 50–80 years of age and have a history of a previous skin tumor. The patient may present with proptosis, diplopia, ptosis, and orbital pain.

#### Orbital Imaging

On CT scan, orbital basal cell carcinoma appears as an irregular, often lobulated, well-defined density extending into the retroseptal space. Less dense cystic spaces can be present and enhancement is moderate. On MRI

**Fig. 12.10.24 Malignant Melanoma.** (A) Recurrent secondary orbital malignant melanoma in an enucleated socket from extrascleral extension of a uveal tumor. (B) Computed tomography scan showing a homogeneous medium density mass filling the orbit.

T1 images, basal cell carcinoma appears as a homogeneous isointense mass. On the T2 images, the tumor produces a somewhat brighter image. Marked enhancement occurs with gadolinium.

## Pathology

Strands of basaloid cells in a dense fibrous stroma extend into the orbit. Basophilic tumor cells are arranged radially with their long axes parallel to each other, creating so-called “peripheral palisading.” Sometimes the tumor lobules have central necrosis or a prominent adenoid pattern.

## Treatment and Prognosis

Localized lesions in the anterior orbit are excised when possible. Heroic attempts to retain visual function frequently result in scarring with a fixed globe. Deep orbital tumors that invest the globe require limited or radical orbital exenteration. With appropriate surgery, prognosis for life is good but recurrences may be seen after many years.

## MALIGNANT MELANOMA

### Key Points

Most malignant melanomas in the orbit are secondary tumors spreading from an intraocular choroidal primary site or from the conjunctiva.<sup>74,75</sup> Primary melanomas are extremely rare but can arise from a cellular blue nevus or in the setting of oculodermal melanocytosis. Occasionally malignant melanoma may metastasize to orbital structures from distant sites. In advanced cases proptosis, ptosis, chemosis, ophthalmoplegia, and orbital pain may be seen (Fig. 12.10.24).

### Orbital Imaging

CT demonstrates a homogeneous orbital mass of moderate density. When extension is from the choroid the mass is typically intraconal and may be infiltrative around orbital structures. A similar and contiguous mass may be seen as a dome or collar-button density within the globe. In cases of prior enucleation for intraocular melanoma, the orbital implant may be displaced forward by the tumor. On MRI images an infiltrative mass is seen that produces a high intensity signal on both T1 and T2 weighted sequences. With gadolinium there is diffuse enhancement.

## Pathology

Choroidal melanoma extending into the orbit through a scleral canal will have the appearance of the primary intraocular tumor, which is usually pigmented. In contrast, melanoma recurrent in the orbit may be composed solely of amelanotic, polygonal or spindle-shaped tumor cells. Paraffin sections can be immunostained for S100 protein and/or HMB-45 (a marker for cutaneous and uveal melanoma) to confirm the diagnosis.

## Treatment and Prognosis

The best treatment is not yet firmly established. Although local resection has been advocated for some well-defined low-grade tumors arising from blue nevi, in most cases a more radical procedure will be needed for cure. This implies a limited anterior exenteration for lesions arising in conjunctiva or a radical exenteration for tumors originating from the choroid with deep orbital invasion. Overall, the prognosis is guarded with a high mortality rate from metastatic spread.

# Enucleation, Evisceration, and Exenteration

12.11

Myron Tanenbaum

## Definitions:

- Enucleation: surgical removal of the entire globe.
- Evisceration: surgical removal of the entire contents of the globe, leaving a scleral shell.
- Exenteration: removal of the entire orbit including the globe, eyelid, and orbital contents—usually performed for malignant tumors.

## Key Features

- Indications for enucleation, evisceration, or exenteration surgery.
- Careful preoperative patient evaluation and counseling.
- Detailed presentation of specific surgical techniques for enucleation, evisceration, and exenteration.
- Postoperative management, and possible surgical complications.

## INTRODUCTION

Enucleation, evisceration, and exenteration surgery all involve the permanent removal of the patient's eye. In this chapter the important aspects of each procedure are emphasized, including:

- Indications for surgery.
- Preoperative patient counseling.
- Surgical techniques.
- Postoperative management.
- Complications of surgery.

## PREOPERATIVE EVALUATION AND DIAGNOSTIC APPROACH

### Indications for Surgery

Enucleation or evisceration surgery may be indicated for a blind painful eye, endophthalmitis, or cosmetic improvement of a deformed eye. In cases of intraocular neoplasms or the treatment of severe ocular trauma with a ruptured globe, where sympathetic ophthalmia is a concern, enucleation is appropriate and evisceration is contraindicated. Other indications for enucleation may include progressive phthisis bulbi, severe microphthalmia, and biopsy in a bilateral process where one eye is blind and the other eye is not as involved.

In the vast majority of situations, the indication for exenteration surgery is to eradicate life-threatening malignancy or life-threatening orbital infection. The extent of the procedure should be explained to the patient, especially which tissues are to be removed (this includes the eyeball, orbital soft tissues, and part or all of the eyelid structures). A summary of the indications for surgery is given in [Box 12.11.1](#).

### Preoperative Counseling

Faced with the permanent loss of an eye, a patient requires the physician's reassurance, caring explanations, and psychological support. The patient (and family) should understand that evisceration and enucleation surgery involve the complete, permanent removal of the diseased or deformed eye. The indication for surgery should be clearly explained. The patient should be informed of the choices between enucleation and evisceration surgery

and of the availability of a variety of orbital implants, including common alloplastic implants,<sup>1,2</sup> newer implants designed to maximize ultimate ocular prosthesis motility,<sup>3,4,5</sup> or autologous tissue orbital implants such as dermis fat.<sup>6</sup>

The patient should understand the risks and benefits of wrapping orbital implants with either autologous tissues or preserved donor tissue and that donor tissues may carry the risks of communicable diseases, such as syphilis, hepatitis, and human immunodeficiency virus. A thorough explanation allows the patient and family to make a well-informed decision regarding surgery.

## ANESTHESIA

Enucleation surgery may be performed using local anesthesia. For psychological reasons, and occasionally for medical reasons, however, general anesthesia is usually employed. Under any circumstance, agents should be used that maximize intraoperative hemostasis, suppress the oculocardiac reflex,<sup>7</sup> and minimize postoperative pain. The author's choice is to instill 10% phenylephrine eyedrops into the conjunctival cul-de-sac to achieve intense vasoconstriction and to infiltrate extensive retrobulbar and peribulbar bupivacaine 0.5% with epinephrine (adrenaline) 1:100 000 and hyaluronidase. After adequate time, an excellent anesthetic and vasoconstrictive effect is achieved.

Most evisceration surgeries are performed under local anesthesia with intravenous sedation. A mixture of lidocaine (lignocaine) 2% with epinephrine 1:100 000, bupivacaine 0.5% with 1:100 000 epinephrine, and hyaluronidase is injected in retrobulbar fashion into the muscle cone. The use of intravenous anesthetic sedatives prevents either the local anesthetic injection or the surgical procedure itself from being unpleasant or producing anxiety.

Exenteration surgery is usually performed under general anesthesia, which may be combined with bupivacaine and epinephrine infiltration to aid hemostasis and provide postoperative analgesia.

### BOX 12.11.1 Indications for Surgery

#### Enucleation

- Blind painful eye
- Intraocular tumor
- Severe trauma with risk of sympathetic ophthalmia
- Phthisis bulbi
- Microphthalmia
- Endophthalmitis/panophthalmitis
- Cosmetic deformity

#### Evisceration

- As for enucleation, except for intraocular tumors or risk of sympathetic ophthalmia

#### Exenteration

- Cutaneous tumors with orbital invasion
- Lacrimal gland malignancies
- Extensive conjunctival malignancies
- Other orbital malignancies
- Mucormycosis
- Chronic orbital pain
- Orbital deformities

## SPECIFIC TECHNIQUES

### Enucleation

The indications for enucleation surgery and important aspects of preoperative counseling have already been discussed. Here, two surgical techniques are described:

- Enucleation with placement of a simple sphere implant.
- Enucleation with placement of a sclera-wrapped porous implant for improved motility.

#### Enucleation With Simple Sphere Implant

A self-retaining lid speculum is placed to expose the entire epibulbar surface. A 360° conjunctival peritomy is performed (Fig. 12.11.1). Tenon's fascia is bluntly dissected away from the sclera in all four quadrants. Each of the four rectus muscles is sequentially gathered on a muscle hook, secured with a double-armed 6-0 Vicryl suture, and detached from the globe. The superior oblique tendon is severed and detached from the globe. The inferior oblique muscle should be hooked and secured with a 6-0 Vicryl suture, detached, and saved for later attachment to the inferior

**Fig. 12.11.1 Enucleation Procedure.** Following a 360° conjunctival peritomy, a small pair of tenotomy scissors is used to dissect bluntly Tenon's fascia in all four quadrants.

border of the lateral rectus muscle. This use of the inferior oblique muscle is perhaps more important as an eventual “hammock” for the orbital implant than to enhance meaningfully anophthalmic socket motility.

After the extraocular muscles are detached, the surgeon is ready to sever the optic nerve. Anterior traction on the globe is useful when cutting the optic nerve and can be achieved with a curved hemostat applied to the medial rectus tendon. It is the author's preference to clamp the optic nerve with a curved hemostat inserted behind the globe in the superonasal direction (Fig. 12.11.2). With the hemostat in place, a slender, curved pair of Metzenbaum scissors is used to transect the optic nerve, and the entire eyeball is removed. The surgeon should inspect the entire globe for intactness and/or unusual findings before submitting the specimen for histopathological examination. Malleable retractors are placed so the still clamped cut edge of the optic nerve can be visualized directly. The central retinal vessels are cauterized to obtain meticulous hemostasis before removal of the clamp (Fig. 12.11.3). If the optic nerve is not clamped, such as for intraocular tumors, orbital packing with direct pressure for 5–10 minutes can be applied to achieve adequate hemostasis. In select enucleations, as with tumors in contact with the optic disc or with retinoblastoma-containing eyes, it may be necessary to obtain a long segment of optic nerve.<sup>8</sup>

For the average-sized adult orbit, a 20 mm polymethyl methacrylate orbital implant is usually adequate. The implant type and size can, of course, vary, and it may also be wrapped in either autologous fascia or donor sclera. The orbital implant is inserted behind posterior Tenon's fascia through the central rent left by cutting the optic nerve. Multiple interrupted 6-0 Vicryl sutures securely close posterior Tenon's fascia that overlies the orbital implant.

Each of the four rectus muscles is sutured to the adjacent fornix by passing the previously placed double-armed 6-0 Vicryl sutures full thickness through Tenon's fascia and conjunctiva (Fig. 12.11.4). This will provide motility to the ocular prosthesis. Care should be taken to avoid advancing the superior rectus suture too close to the midline to avoid inadvertent tension or traction on the superior rectus muscle, which could induce an upper lid ptosis. After anterior Tenon's fascia is closed in the midline with 6-0 Vicryl sutures (Fig. 12.11.5),<sup>9</sup> the conjunctival edges are loosely reapproximated with a 6-0 plain gut running suture.

A broad-spectrum ophthalmic antibiotic ointment is applied to the conjunctiva. A medium-sized clear, acrylic lid conformer is placed and a firm pressure bandage applied over the socket. The pressure bandage remains intact for 3–4 days postoperatively, and, upon its removal, the patient uses topical cool compresses with crushed ice. Pain medication is prescribed as appropriate. This perioperative and postoperative management regimen allows the large majority of enucleation procedures to be performed as outpatient procedures, with adequate control of postoperative pain.

#### Enucleation With Porous Implant

The purpose of the porous implant, such as the hydroxyapatite, porous polyethylene, or aluminum oxide implant, is to allow the potential for

**Fig. 12.11.2 Each of the Four Rectus Muscles Is Tagged With a Double-Armed 6-0 Vicryl Suture and Detached From the Globe.** Some 4-0 silk sutures may be placed through the medial and lateral recti muscle stumps to provide anterior traction on the globe, as a slender, curved hemostat is used to clamp the optic nerve.

**Fig. 12.11.3** The Globe Has Been Removed and Cautery Is Applied to the Optic Nerve Stump to Maintain Meticulous Hemostasis.

**Fig. 12.11.4** An Orbital Implant Has Been Placed Behind Posterior Tenon's Fascia. This layer is then closed with multiple interrupted 6-0 Vicryl sutures. The four rectus muscle stumps remain free with the 6-0 Vicryl sutures attached.

maximum motility of the ocular prosthesis.<sup>10,11</sup> The microstructure of these implants allows fibrovascular ingrowth of the host tissues into the implant.<sup>3,12</sup> Once the implant is well vascularized, it can be secondarily fitted with a motility peg. This motility peg is then coupled to the ocular prosthesis to *maximally enhance* prosthesis motility.

A standard enucleation technique is performed, as already described. The socket may be "sized" using sterile trial spheres, but in most cases an 18- or 20-mm implant is appropriate. Keep in mind that wrapping the implant with sclera or fascia adds approximately 1–1.5 mm to the overall diameter of the implant.

If a wrapping material such as sclera is used, the scleral shell should be cut to the appropriate size and shape to enclose the implant securely. Multiple interrupted 6-0 Vicryl sutures are suitable for securely closing the sclera. The round opening where the cornea was removed from the wrapping scleral shell should be positioned posteriorly. Rectangular windows, approximately 2–4 mm, are cut through the sclera located within 8–10 mm

**Fig. 12.11.5** Enucleation Surgery—Final Closure. The 6-0 Vicryl rectus sutures are sewn onto their respective fornices by passing the sutures through Tenon's fascia and conjunctiva. The anterior Tenon's is closed with 6-0 Vicryl and the conjunctiva with a running 6-0 plain suture.

from the anteriormost apex of the implant for attachment of the extraocular muscles. To promote further fibrovascular ingrowth into a hydroxyapatite implant, a handheld 20-gauge needle is used to create drill holes at the site of each window and at the site of the posterior round corneal window.<sup>13</sup>

The wrapped or unwrapped implant is placed into the anophthalmic orbit and the four rectus muscles are secured to the anterior lip of the corresponding rectangular scleral window. Anterior Tenon's fascia is sutured over the implant with multiple interrupted 6-0 Vicryl sutures. The conjunctiva can be closed with a loosely running 6-0 plain suture, which is tied and cut on each end. Implant exposure is a significant problem with porous implants<sup>14</sup> compared with alloplastic sphere implants,<sup>15</sup> thus emphasizing the need for meticulous closure of Tenon's. As is the case with any enucleation procedure, a polymethyl methacrylate lid conformer is placed in the conjunctival cul-de-sac with broad-spectrum antibiotic ointment and a pressure bandage applied.

The unique properties of porous implants allow fibrovascular ingrowth and integration of the implant with the ocular prosthesis. Without placement of the motility peg, no demonstrable motility difference exists between a porous implant and a polymethyl methacrylate implant.<sup>2,16</sup> Thus porous implants are most appropriate for patients who express a strong interest in eventual second-stage procedure to maximize prosthesis motility. These titanium motility pegs are surgically inserted after adequate fibrovascular ingrowth into the hydroxyapatite implant has occurred.<sup>17–19</sup>

Surveys of oculoplastic surgeons in the United States and United Kingdom show that less than 10% of porous implants are currently pegged because of excessive peg complications. If a peg is not placed, a simple and inexpensive silicone implant with muscles directly attached can provide equal motility with fewer potential complications.<sup>20</sup>

## Evisceration

### Overview

Evisceration is the surgical technique that removes the entire intraocular contents of the eye while leaving the scleral shell and extraocular muscle attachments intact. Evisceration surgery is a simpler procedure than enucleation surgery and offers better preservation of the orbital anatomy<sup>21</sup> and natural motility of the anophthalmic socket tissues. A combined enucleation and evisceration technique<sup>22</sup> and modified evisceration techniques<sup>23</sup> have been described as an alternative, particularly in patients with a phthisical eye.

Evisceration is contraindicated in cases of documented or suspected intraocular malignant tumors. A preoperative ocular ultrasound is mandatory to rule out occult malignancy. Evisceration surgery may be more difficult in an eye with severe phthisis or scleral contracture or that is severely deformed. Finally, the issue of potential sympathetic ophthalmia should be considered.<sup>24–26</sup> Evisceration surgery in a recently injured eye carries a definite small risk of sympathetic ophthalmia in the opposing eye

because some uveal tissue is always left behind in scleral canals.<sup>24</sup> Except in these situations, evisceration can be considered as an alternative to enucleation.<sup>27,28</sup>

### Surgical Technique

The procedure begins with a 360° conjunctival peritomy (Fig. 12.11.6). Tenon's fascia is bluntly separated from the underlying sclera in all four quadrants. A full-thickness incision around the corneal limbus is made with a sharp scalpel blade and the entire corneal button removed. The sclera is grasped with a forceps, and a cyclodialysis spatula is used to separate the iris root and ciliary body from the sclera. The remainder of the uveal tissue is dissected away from the scleral wall back to the attachment around the optic nerve with an evisceration spoon (Fig. 12.11.7). The intraocular contents are lifted from the scleral shell and submitted for histopathological examination. All remaining uveal tissue is carefully removed from the scleral shell with a small curette or the sharp end of a caudal periosteal elevator. Cotton-tip applicators saturated with 70% ethanol may be used to cleanse the interior of the scleral shell and denature any remaining uveal pigmented tissue. Cautery is applied if needed to control the oozing of blood.

A polymethyl methacrylate spherical implant is placed in the evisceration scleral shell (Fig. 12.11.8). When the cornea is removed, it is unusual to place an implant larger than 14–16 mm. The scleral edges are closed with multiple interrupted 6-0 Vicryl sutures, with the medial and lateral scleral edges cut to reduce any dog ears (Fig. 12.11.9). The conjunctiva is gently closed with a running 6-0 plain gut suture. If a larger implant is desired, it is necessary to perform radial relaxing sclerotomy incisions posteriorly<sup>29</sup> between the rectus muscles (Fig. 12.11.10). If a porous implant is used, such sclerotomy openings are necessary to enhance vascular ingrowth.<sup>30</sup>

Multiscleral flap evisceration techniques safely allow placement of 18–20 mm spherical implants in most cases.<sup>31,32</sup>

Dressing and postoperative care are as for enucleation.

### Exenteration

#### Overview

Exenteration surgery involves complete removal of the eyeball and a total or subtotal removal of the retrobulbar orbital soft tissues and most or all of the eyelids.<sup>33,34</sup> The most common indication for exenteration surgery is for the treatment of epithelial malignancy with orbital invasion.<sup>35,36</sup> Because

**Fig. 12.11.6 Evisceration Procedure.** A 360° conjunctival peritomy is made, followed by complete excision of the corneal button.

**Fig. 12.11.8 A Sphere Introducer Is Used to Place the Orbital Implant Into the Evisceration Scleral Shelf.**

**Fig. 12.11.7 An Evisceration Spoon Is Used to Detach the Ciliary Body and Bluntly Elevate the Choroid From the Scleral Wall.**

## EVISCERATION PROCEDURE – CLOSURE OF THE SCLERAL SHELL

**Fig. 12.11.9** The Scleral Opening Is Closed With Multiple Interrupted 6-0 Vicryl Sutures. Conjunctiva is subsequently closed over the scleral wound using running 6-0 plain gut sutures.

## EVISCERATION PROCEDURE – RELAXING SCLEROTOMY

**Fig. 12.11.10** A Unipolar Cautery Is Used to Incise Relaxing Sclerotomy Slits to Expand the Scleral Shell. This sclerotomy technique to enlarge the scleral shell volume is “optional” with polymethyl methacrylate sphere implants. Sclerotomy slits are “mandatory” when hydroxyapatite spheres are used to facilitate vascular ingrowth.

## EXENTERATION – SURGICAL PLANES OF DISSECTION

**Fig. 12.11.11** Cross-Sectional View of Surgical Planes of Dissection for Exenteration Surgical Techniques. Total exenteration, subtotal exenteration with sparing of myocutaneous eyelid tissue, and enucleation with partial socket ablation.

in many cases this procedure is done for recurrent tumor, the need for exenteration can be minimized by aggressive primary management of the initial lesion.<sup>37</sup>

When exenteration is performed for orbital malignancies, periorbital is usually excised to remove completely all potentially involved tissues. The bare orbital bone can slowly heal by second intention, but in most situations the exenterated orbit is covered with a split-thickness skin graft at the time of the procedure. As there is potential for recurrent tumor, reconstruction with thick, bulky tissue grafts or flaps, which could obscure recurrence, is avoided. In very select situations, however, a variety of ancillary reconstructive techniques may be of use, such as those involving

ipsilateral temporalis muscle flaps,<sup>38</sup> free dermis-fat grafts,<sup>39</sup> latissimus dorsi myocutaneous free flaps,<sup>40</sup> osteofasciocutaneous fibula flap<sup>41</sup>, osseointegrated implant techniques,<sup>42</sup> and other procedures.<sup>43–48</sup>

### Surgical Technique

The area of the proposed exenteration incision is marked with adequate wide margins where necessary for tumors, yet with preservation of as much normal periocular soft tissue as possible (Fig. 12.11.11). If necessary, adjacent areas of the medial canthus, temple, or forehead are included in the excision site. When surgery is necessary for a conjunctival or deep orbital tumor, a subciliary incision around the eyelid margins and wrapping

**Fig. 12.11.12 Exenteration Procedure.** A 360° skin incision is made down to the periosteum of the orbital rim. A periosteal elevator is used to begin reflecting the superior periorbital tissue downward.

**Fig. 12.11.13 Bony Orbit Demonstrating the Normal Sites of Increased Resistance to Dissection During Orbital Exenteration.**

around the inner canthus preserve the eyelid skin and orbicularis muscle, which can be used for reconstruction.<sup>46</sup>

The skin is incised along the mark, and any orbicularis muscle to be spared is dissected in a suborbicular plane. The dissection is carried down through periorbital to expose the orbital rim. A periosteal elevator is used to elevate periosteum over the orbital rim and periorbital from the orbital walls (Fig. 12.11.12). Firm attachments to bone are encountered at the lateral orbital tubercle, the superior oblique trochlea, the medial canthal tendon, the distal lacrimal sac as it enters the bony nasolacrimal canal, the inferior oblique origin near the posterior lacrimal crest, and the superior and inferior orbital fissure attachments (Fig. 12.11.13; see Chapter 12.2). Except for these sites of resistance, the periorbital can be elevated quite easily. Medially, the surgeon should use particular care when elevating periorbital so as to avoid inadvertent penetration of the lamina papyracea into the ethmoid sinus air cells, which could result in a chronic sino-orbital fistula.

Superiorly, the superior orbital bone may be quite attenuated in elderly patients, and atrophic bony defects may be present. Monopolar cautery to

the orbital roof should be avoided, as this may cause inadvertent cerebrospinal fluid leakage.<sup>49</sup> It is generally safe to use bipolar cautery along the orbital roof and deep orbital tissues without the risk of cerebrospinal fluid leakage.

The periorbital lining is mobilized along all orbital walls toward the orbital apex. The dissection and mobilization of soft tissues must extend posteriorly beyond the extent of tumor invasion. A thin, curved hemostat can be used to clamp the apical tissues while a slender pair of Metzenbaum scissors is used to excise the exenteration specimen anterior to the clamp (Fig. 12.11.14). An enucleation snare may be used to incise the apical stump to complete the severing of the exenteration specimen.<sup>50</sup> When necessary, frozen section pathology analysis of the apical stump tissues should be used to verify that the margins of resection are free and clear of neoplasm. The orbital bone should be carefully inspected for subtle bone pitting or other signs of bone erosion or destruction.

In patients who have very bulky or massive orbital neoplasms, exenteration may be difficult, with little space in which to separate periorbital from orbital bone. It may be helpful here first to enucleate the eyeball to make enough room for access to the deeper apical soft tissues under good visualization.

In most patients, the orbit will be lined with a split-thickness skin graft harvested from the anterior surface of the thigh. It is usually preferable to expand the skin graft in a mesh. Multiple interrupted 6–0 Vicryl sutures secure all residual host skin edges to the meshed skin graft. The graft is tamponaded within the orbit with a Telfa dressing and Xeroform gauze packing under pressure.

If the upper lid and lower eyelid skin and muscle are preserved, it may be possible in elderly patients with a lot of loose eyelid skin simply to suture the skin edges together and then place a pressure dressing to tamponade the myocutaneous edges against the bare bone. In selected cases, the socket can be allowed to heal by granulation.<sup>51</sup>

### Postoperative Management

The orbital pack and pressure dressing should remain in place for approximately 5–7 days. Following removal of the dressing, the patient can use gentle hydrogen peroxide rinses to cleanse the socket. Generally, these orbits heal best when left open to the air, so the patients should wear a patch only when going out in public. The surgeon should remain vigilant to the possibility of infection of the skin graft, especially by *Pseudomonas*, *Staphylococcus*, or *Streptococcus*. Systemic antibiotics may be necessary if these infections arise. In some patients, the exenterated orbit retains chronic, moist, ulcerated areas intermixed with areas of healthy keratinizing epidermis. The use of a gentle handheld hair dryer can help “cure” these slower-healing areas.

A combined eyelid–ocular prosthesis can be made by an anaplastologist. Many exenteration patients prefer simply to wear a black patch.

**Fig. 12.11.14 Periorbital Has Been Elevated for 360°.** Forward traction is applied to the orbital contents as a hemostat is used to clamp the apical orbital tissues.

## COMPLICATIONS

### Evisceration

Postoperative infection is always of concern when evisceration surgery is performed in the setting of endophthalmitis or panophthalmitis. The use of broad-spectrum systemic antibiotics usually minimizes this risk, and the surgeon can generally use a primary orbital implant. Postoperative extrusion of the orbital implant is a complication of evisceration surgery that may be related to postoperative scleral shell shrinkage, to poor wound healing of the scleral edges, or to improper selection of the orbital implant size. Postoperative pain is more common when the cornea is retained.

### Enucleation

Orbital implant exposure<sup>52</sup> or extrusion is another complication of enucleation surgery.<sup>14,53</sup> Meticulous attention to careful Tenon's fascia wound closure and the proper selection of implant size are important principles in avoiding this outcome. Risk of implant extrusion is increased with prior irradiation treatment of the eye and orbit, severe traumatic injuries to the eye and orbit, and severe eye and orbital infections. Careful surgical technique is very important in cases involving secondary orbital sphere implantation following enucleation (or evisceration) surgery.<sup>54</sup> Secondary orbital implants carry a much higher complication rate (e.g., implant extrusion or migration) than primary orbital implants.<sup>55</sup> Long-term complications of the anophthalmic socket are numerous, including generalized volume deficiency of the anophthalmic socket, lower eyelid laxity with poor prosthesis support, orbital implant migration, upper eyelid ptosis, chronic conjunctivitis, and mucoid discharge. Integrated orbital implants (e.g., hydroxyapatite) with motility pegs have high complication rates, including pyogenic granuloma formation around the peg and chronic anophthalmic socket secretions.

### Exenteration

Exenteration surgery carries the risk of severe blood loss. It is important preoperatively to discontinue aspirin and all other medicines that could

adversely affect blood clotting. Other complications unique to exenteration surgery include cerebrospinal fluid leakage via orbital roof transgression of the dura and chronic sino-orbital fistulas through the region of the lamina papyracea and ethmoid sinus air cells.<sup>32</sup> Free skin grafts are susceptible to infection during the first few weeks of healing. Patients may require treatment with broad-spectrum systemic antibiotics for coverage of *Staphylococcus*, *Streptococcus*, *Pseudomonas*, and other bacteria. The administration of systemic antibiotics is combined with maintenance of vigorous topical hygiene of the split-thickness skin graft using hydrogen peroxide rinses. Long term, the surgeon should always remain vigilant for the possible recurrence of tumor.

# The Lacrimal Drainage System

Jeffrey J. Hurwitz, Jane M. Olver

12.12

**Definition:** The tear disposal system of the eye that consists of the punctum, canaliculi, lacrimal sac, and nasolacrimal duct. The eyelids also form a physiological lacrimal pump.

Key Features

- The orbicularis muscle and eyelids act as a lacrimal pump for tear drainage.
- The drainage system is composed of the punctum, canaliculi, lacrimal sac, and lacrimal duct.
- Eyelid malposition or malfunction results in epiphora.
- Stenosis or occlusion results in epiphora.
- Clinical testing localizes the site of obstruction.

Associated Features

- Congenital obstruction is usually caused by an imperforate membrane at the nasal end of the lacrimal duct (valve of Hasner).
- Acquired obstruction may result from chronic fibrosis of the duct, trauma, or previous nasal or sinus surgery.
- Correction of congenital obstruction is typically achieved with a simple probing procedure.
- For acquired obstructions, a dacryocystorhinostomy (DCR) is usually required for permanent resolution.
- Eyelid position, laxity, and malfunction must be assessed.

INTRODUCTION

Under normal circumstances, the tears secreted should equal those eliminated so that neither a dry eye nor symptoms of a watery eye occur. Tearing (a watery eye) may be caused by hypersecretion of tears or decreased elimination, called epiphora (Table 12.12.1). Hypersecretion may result from an increased production of tears from stimulation of the neurophysiological pathway either centrally or as a local reflex. Decreased elimination is caused by reduced passage of tears into or through the lacrimal drainage system, as a result of eyelid malfunction or malposition, or outflow stenosis/obstruction. The cause of the tearing can be estimated by the clinical symptoms and confirmed by clinical signs and tests.

ANATOMY AND PHYSIOLOGY

Tears are secreted by the lacrimal gland, with a 24-hour secretory volume of approximately 10 mL.<sup>1</sup> With blinking, the palpebral aperture closes from

lateral to medial, and tears are pumped along the marginal tear strips of the upper and lower lids toward the lacrimal lake at the inner canthus. In the normal resting state, most tears are lost by evaporation, and only a small volume passes down through the nasolacrimal passageways.

Tears pass from the lacrimal lake into the canaliculi through the puncta mainly by capillarity. It is important that the puncta of each lid contact the opposite lid on closure and thereby become physiologically occluded. When the lids separate, capillarity draws the tears into the empty canaliculi. Tears then flow to the common canaliculus and lacrimal sac due to a combination of factors<sup>2-5</sup>:

- A change in the caliber of these passages.
- A change in pressure within the canalicular passages.
- A pumping function (lacrimal pump) of the orbicularis muscle that surrounds these passages.

Tears flow into the inferior meatus of the nose through the effect of the lacrimal pump, gravity, and to a lesser extent pressure changes within the nose due to respiration. Valves within the drainage system permit only one-way flow of tears.

EVALUATION OF EPIPHORA

Clinical History

The history of symptoms associated with tearing is important. Outflow obstruction is typically worse in the morning, when outside, or in the cold. The tears usually drain down medially along the tear trough.

Pain at the side of the nose suggests dacryocystitis, but pain in the eye may be due to foreign bodies, keratitis, recurrent corneal erosion, iritis, or glaucoma. Itchiness suggests an allergic problem rather than lacrimal obstruction. Grittiness and burning of the eyes associated with tearing suggest a lid margin and tear film problem, such as occurs in blepharitis and meibomian gland dysfunction, keratitis sicca, or dysthyroid eye disease.

A history of topical medication such as echothiophate iodide (Phospholine Iodide), epinephrine (adrenaline), or pilocarpine drops is important, because they may produce lacrimal obstruction. Chemotherapy such as 5 fluorouracil (5-FU) and radiotherapy can cause obstruction in the canaliculi. Photodynamic therapy also has been associated with canalicular stenosis.

Physical Examination

Eyelids

Poor orbicularis muscle tone and reduced lacrimal pump dysfunction may be presumed if the lid can be pulled more than 8 mm away from the globe, if there is decreased snap-back, or if there is frank ectropion or floppy eyelid syndrome. The puncta should normally be directed backward into the lacrimal lake to catch the tears. Lesions of the caruncle such as megacaruncle may interfere with tear drainage. Blepharitis and meibomian gland dysfunction with dry eyes may cause secondary oversecretion of tears. It is important to detect and correct any eyelid malposition or laxity and treat eyelid margin disease well to reduce watering before embarking on lacrimal surgery.

Lacrimal Passages

Facial asymmetry suggests congenital or traumatic anatomical blockage of the nasolacrimal canal. Any mass at the inner canthus should be palpated to determine whether it is soft (indicating mucus) or firm (suggesting a possible tumor) and whether it is compressible or noncompressible. Orbital signs such as proptosis, displacement of the globe, diplopia,

TABLE 12.12.1 Causes of Tearing

Lacrimation (Hypersecretion)	Epiphora (Decreased Tear Elimination)	
	Anatomical factors	Physiological dysfunction
Anterior blepharitis and meibomian gland dysfunction Corneal foreign bodies Corneal irritation with dry spots Ocular surface inflammation Refractive errors Thyroid dysfunction	Punctal, canalicular or nasolacrimal duct strictures or obstructions Foreign bodies (e.g., lacrimal stones) Extrinsic or intrinsic tumors	Orbicularis muscle weakness Punctal or eyelid malpositions Nasal obstruction with normal lacrimal pathway

and ptosis could indicate that the lacrimal lesion involves the orbit or vice versa.

### Nose

The endoscopic nasal examination is an essential part of every lacrimal evaluation. Nasal and sinus conditions, which range from infections and inflammations to tumors, may result in epiphora. Coexistent sinus disease often causes chronic inflammation and narrowing of the nasolacrimal duct. Symptoms include anosmia (loss of smell), epistaxis, anesthesia around the roof of the nose, and nasal obstruction, which may occur with intranasal tumor.

## Clinical Diagnostic Tests

### Tear Tests

#### Dye Tests

The tear meniscus can be seen elevated with fluorescein 2% instilled into the conjunctival fornix when there is delayed outflow.

The fluorescein dye retention test is a physiological test where more fluorescein-stained tears are visible on the white of the eye after 3 to 5 minutes when there is outflow narrowing or obstruction. Often the tears overflow medially down the tear trough in outflow obstruction and laterally over the outer cheek when there is an eyelid cause such as wick syndrome caused by excess upper eyelid overhanging skin

### Excretory Tests

#### Lacrimal Syringing

In syringing, a 27-gauge lacrimal irrigation cannula is passed into the punctum and advanced through the canaliculus to the medial wall of the lacrimal sac fossa (see Chapter 12.2). During its passage the examiner can feel if there is a small pop at the entry of the common canaliculus into the sac that is consistent with a membranous obstruction. If there is a complete block affecting the common canaliculus, a soft stop is felt as the cannula does not reach bone. If the cannula hits bone, called hard stop, the obstruction is probably in the sac or the duct. Be gentle, as the medial wall of the sac can be tender especially when there is some inflammation of the sac. If there is an obvious dacryocystitis or nonexpressable mucocele, avoid syringing beyond the canaliculus as it will be very tender for the patient.

Clear water or saline is gently irrigated through the cannula. If fluid passes into the nose without reflux, the system is totally patent. If fluid passes into the nose with resistance and reflux occurs, the system is anatomically patent but physiologically stenotic (partially occluded). If no fluid passes into the nose but it all comes back through either punctum, complete nasolacrimal duct obstruction is present.

### Jones Fluorescein Dye Test

The original Jones I and II<sup>5</sup> dye tests are now rarely used. Instead the endoscopic Jones test is performed.<sup>6</sup>

A drop of fluorescein is placed into the conjunctival cul-de-sac. The nose is examined using the Hopkins rigid nasal endoscope (4 mm) after 3 minutes to determine whether the dye has passed through the lacrimal system spontaneously, which indicates that it is functionally patent. The endoscope is directed at the inferior meatus after nasal decongestion to shrink the inferior meatus mucosa.

In the second part of the test, the cannula is placed in the sac and the system is irrigated. Any fluid that passes into the nose during irrigation will be subsequently seen with the nasal endoscope. If no fluorescein is visualized, this suggests that it did not pass into the sac during the initial fluorescein test, so the problem is likely in the upper (canalicular) system. If fluorescein is present, this indicates that it reached the sac during the initial test and that the upper system is probably normal, meaning that the problem is in the lower (sac, duct) system. Although the endoscopic Jones test is useful, it is interpreted along with the tear meniscus, the fluorescein dye retention test, and other tests and radiological investigations such as lacrimal scintigraphy (nuclear imaging) and dacryocystography.

The tests help point to the diagnosis and location of the narrowing or obstruction and hence help surgical planning.

### Endoscopy

Nasal endoscopy using a rigid telescope is useful to observe the anatomy of the opening of the nasal lacrimal duct in the inferior meatus and to diagnose any disease within the nose itself (Fig. 12.12.1). If a lacrimal drainage operation is contemplated, the endoscope is the best method to assess the future surgical site. Should tearing persist following lacrimal surgery, it is useful to view the size and location of the previous dacryocystorhinostomy

**Fig. 12.12.1 Endoscopy.** Endoscopic view of the nose demonstrates the nasal septum (S), lateral wall, and turbinates (T).

**Fig. 12.12.2 Lacrimal Scan.** Complete obstruction on the left side and stenosis on the right side.

(DCR) opening using an endoscope to determine whether the opening is obstructed by fibrous tissue, polyps, granuloma, or foreign bodies.

## Diagnostic Imaging

### Nuclear Lacrimal Scan

Also called nuclear lacrimal scintigraphy, this is a physiological test of lacrimal function. It does not demonstrate anatomical structures but can help localize whether eyelid, punctual, presaccal, or postsaccal obstruction is present. A drop of technetium-99m pertechnetate is placed into the palpebral aperture and a pinhole collimator of a gamma camera is used to record its transit to the nose. The lacrimal scan can help determine the extent of delay from a physiological or functional point of view (Fig. 12.12.2).

### Dacryocystography

Dacryocystography (DCG) is extremely useful to determine the exact anatomical site of obstruction or stenosis within the system (Figs. 12.12.3 and 12.12.4) and to visualize any deflection of the passages by diseases of the surrounding structures (Fig. 12.12.5; Box 12.12.1). Injection of a water-soluble contrast material (digital subtraction dacryocystography)<sup>7</sup> through a catheter demonstrates the lacrimal drainage pathways and outlines any anatomical abnormalities. This test does not evaluate physiological function.

### Computed Tomography

High-resolution computed tomography (CT) in the axial and coronal planes is a useful anatomical study to assess those patients who have

**Fig. 12.12.3 Dacryocystogram.** Complete obstruction of the lacrimal drainage pathways at the medial common canalicular level on the right side.

**Fig. 12.12.4 Dacryocystogram.** Stenosis at the sac-duct junction is greater on the left side than on the right.

**Fig. 12.12.5 Dacryocystogram.** Medial deflection of contrast material within the right sac indicates sac stones.

#### BOX 12.12.1 Uses of Dacryocystography

- Complete obstruction where the site of block (canalicular vs sac) cannot be determined clinically
- Incomplete obstruction where the area of stenosis cannot be localized on clinical testing
- In cases of suspected lacrimal sac tumors, to visualize a filling defect
- In adnexal disease, to image compression or deflection of the sac or duct

diseases in the structures adjacent to the nasolacrimal drainage pathways (Fig. 12.12.6).<sup>8</sup> Injection of the canaliculi with contrast provides simultaneous visualization of the lacrimal drainage system (CT-DCG).<sup>9</sup>

## OBSTRUCTIONS OF THE LACRIMAL SAC AND DUCT

### Congenital Obstruction

Congenital nasolacrimal obstruction is due to an imperforate membrane at the valve of Hasner into the inferior meatus, which usually opens spontaneously at the time of birth. Sometimes this may persist into adult life. If spontaneous resolution does not occur by age 1 year, the patient may be treated by probing through the membrane. Probing and syringing is often monitored endonasally using the rigid endoscope because there may be an intranasal cyst in the inferior meatus that requires opening and draining. With increasing age and after previous failed probings, the likelihood of having to treat the obstruction with a DCR increases.

### Acquired Obstruction

Acquired obstructions of the sac and duct may be classified as nonspecific (idiopathic) obstructions and specific obstructions.

#### Nonspecific Acquired Obstruction

The evolution of nonspecific lacrimal sac and nasolacrimal duct inflammation from an early inflammatory stage through an intermediate phase to a late fibrotic stage has been proposed by Linberg and McCormick.<sup>10</sup> The early phase is characterized by vascular congestion, lymphocytic infiltration, and edema. These changes tend to occur at the superior aspect of the nasolacrimal canal just beneath the point where the sac passes into the nasolacrimal intraosseous duct. This occurs more commonly in older patients. It is more common in women than in men. It has also been suggested that it is more common in people from lower socioeconomic levels.<sup>11</sup> Inflammatory conditions that affect the mucosa in the inferior meatus of the nose also may involve the respiratory-like mucosa of the inferior aspect of the nasolacrimal canal, thereby leading to obstruction.

**Fig. 12.12.6 Tearing Secondary to Neoplasm.** (A) Patient with right-sided tearing and a mass at the inner canthus. The system was fully patent to syringing. (B) Computed tomography scan in this patient demonstrates an ethmoidal orbital plasmocytoma with compression of the lacrimal sac.

### Specific Acquired Obstruction

Specific causes of nasolacrimal drainage system obstruction include inflammatory diseases such as sarcoidosis and Wegener's granulomatosis affecting the mucosal lining of the nose, duct, and sac.<sup>12</sup> Sarcoidosis is often treated with systemic corticosteroids before a DCR becomes necessary, and the Wegener's is treated either with dacryocystectomy and removal of all involved mucosa or with a full DCR, as they often have a chronic discharge from mucocele or dacryocystitis.

Infection, trauma, surgical injury, and foreign bodies, such as retained silicone or eyelashes, also may cause obstruction.<sup>12</sup> Lacrimal stones or tumor are to be suspected in younger persons aged 30 to 45 years with unilateral tearing. However, primary neoplasms of the lacrimal sac and duct or secondary tumors arising in the adjacent sinuses are rare causes of obstruction (Box 12.12.2).

### Dacryocystitis

Dacryocystitis is acute, subacute, or chronic. It may be localized in the sac, extend to include a pericystitis, or progress to anterior orbital cellulitis. It very rarely causes posterior orbital cellulitis with proptosis and muscle limitation. When dacryocystitis is localized to the sac, a palpable painful swelling occurs at the inner canthus (Fig. 12.12.7) and obstruction is present at the junction of the nasolacrimal sac and duct. When the infection develops, the lateral expansion of the nasolacrimal sac tends to push on the common canaliculus and produce a kink within it, with the result that the sac is no longer reducible, called nonexpressible. Approximately 40% of initial attacks do not recur, but in the other 60% of patients, repeated attacks occur. Chronic dacryocystitis may be the end stage of acute or subacute dacryocystitis, but it may present initially as a subclinically infectious cause of nasolacrimal duct obstruction. A common organism involved is *Staphylococcus aureus*. In some cases, especially in young women, stones may develop that lead to intermittent attacks of dacryocystitis, termed acute dacryocystic retention syndrome.

In dacryocystitis with pericystitis, percolation of infected debris occurs through the mucosal lining of the wall of the sac, and infection around the

- Lymphoma

sac is present. The infection may spread to the anterior orbit and produce a tremendous amount of eyelid swelling (Fig. 12.12.8). If the infection proceeds posterior to the orbital septum, a true orbital cellulitis may occur, resulting in globe proptosis or displacement, afferent pupillary defect, motility disturbance, optic neuropathy, and even blindness.

The treatment is both medical (systemic antibiotics) and surgical. Temporary surgical relief is obtained by draining the dacryocystitis via the skin and packing the cavity. Increasingly, surgeons are performing early endoscopic, endonasal internal drainage.

## TREATMENT OF LACRIMAL SAC AND DUCT OBSTRUCTION

### Congenital Nasolacrimal Obstruction

More than 90% of patients with congenital nasolacrimal obstruction undergo spontaneous resolution by age 1 year.<sup>13</sup> Therefore, except under extreme circumstances, initial probing should be postponed until this age. Congenital amniocoeles usually resolve on their own and rarely require probing. Persistent swelling at the medial canthus may represent a widened nasolacrimal duct and dilated inferior meatus cyst that requires endoscopic marsupialization.

Probing is performed more easily with the infant under general anesthesia. The probe is passed into the lower canaliculus with the lid stretched laterally. The probe is advanced to the lacrimal bone. It is turned past the 90° angulation and advanced inferiorly until it perforates the membrane at the lower end of the nasolacrimal duct. Fluorescein-tinted irrigation saline is introduced to see whether it passes into the inferior meatus, or metal-to-metal contact may be obtained by inserting a probe in the nose. The success rate of probing is greater than 90%. If this fails, however, one should wait 3 months before doing another procedure, during which time most cases of seemingly failed probing resolve spontaneously. Endoscopic monitoring of syringe and probing is recommended for second procedures because the probe may have remained in the lateral wall or the inferior meatus or merely perforated a small hole in the membrane or cyst originally. Direct view of the inferior meatus enables thorough drainage.

If the repeat probing does not proceed easily, Silastic tubes should be placed and left for at least 3 months (preferably 6 months). If these tubes fail and the child is still tearing, a DCR is performed at a later date.

### Acquired Nasolacrimal Obstruction

Quiet, progressive nasolacrimal-duct stenosis and obstruction is treated by DCR.

After an attack of dacryocystitis, symptoms may resolve spontaneously. If not and syringing demonstrates a persistent block, DCR is indicated.

In the presence of acute or chronic dacryocystitis, first treat the infection with an antistaphylococcal agent such as oral cloxacillin. If post-septal orbital cellulitis is present, a CT scan is obtained to rule out an orbital abscess and intravenous antibiotics are used. If the infection does not resolve and perforation is impending, a dacryocystotomy (external

Fig. 12.12.8 A Patient Who Has Dacryocystitis and Orbital Cellulitis. Ocular mobility is limited, indicating infection posterior to the orbital septum.

drainage) or early endoscopic, endonasal DCR is performed. For dacryocystotomy, after lidocaine (lignocaine) is injected, a cruciate incision is made directly over the lacrimal sac and the debris within the sac is aspirated and curetted. Transcutaneous aspiration of sac contents for culture may be done with a No. 22 needle or the end of a 1 mL syringe.

Definitive treatment of complete obstruction with dacryocystitis is DCR.<sup>14,15</sup>

## Dacryocystorhinostomy

DCR is an operation whereby the lacrimal sac is drained into the nose via a bypass conduit called the ostium or rhinostomy as an opening is made in the lacrimal fossa and ascending process of the maxilla, which is lined with lacrimal sac and nasal mucosa.<sup>16</sup> The classic transcutaneous procedure of Toti<sup>17</sup> has undergone many minor modifications, but the basic operation has withstood the test of time and has a high success rate of 93% to 95%.<sup>18</sup> It may be performed with the patient under general or local anesthesia.<sup>19</sup> In either case, the nose is anesthetized and decongested before surgery.

The procedure is well described elsewhere.<sup>20,21</sup> An incision as small as 8 mm is made on the side of the nose below the medial canthal tendon or within the tear trough, and the dissection is carried down to bone. The periosteum is reflected from the anterior lacrimal crest to reveal the lacrimal sac fossa. The sac is then reflected laterally.

The nasal space is entered by pushing a blunt instrument such as a Traquair periosteal elevator through the suture line between the lacrimal bone and the frontal process of the maxilla. Kerrison punches are used to remove bone between the sac fossa and the nose to create an opening large enough to anastomose the sac and nasal mucosa. Flaps are created in the medial sac wall and in the adjacent nasal mucosa. The posterior flaps and then the anterior flaps of the sac and nasal mucosa are sutured together to form a mucosa-lined opening across the ostium (Fig. 12.12.9). Intervening anterior ethmoid air cell (Agger nasi) may have to be removed for access and partial anterior turbinectomy done adjunctively. Silicone tubes usually are not necessary, but if desired, they can be placed at this time and left in for 2 to 4 weeks. However, recent studies have shown that silicone stents offer no significant increase in success rate.<sup>22</sup>

Indeed, complications of silicone include cheese-wiring, with destruction of the punctum and proximal canaliculus, and dislocation of the tubes laterally over the cornea. In this latter situation, it is better to reposition the tubes than to remove them. If a canalicular DCR is being done or there is marked distal common canalicular stenosis with membranous block, tubes are beneficial.

Nasal packing is usually not necessary unless there is a bleeding point at the end of the operation.

Complications of hemorrhage within the first 24 hours should be controlled by sitting the patient up, pushing fluids and lowering the blood pressure to normal values, and nasal packing. Delayed hemorrhage 4 to 7 days after surgery is due to clot retraction, hence patients are instructed not to blow their nose for 5 to 7 days in case it dislodges that clot.

A hypertrophic cutaneous scar is unusual, but if present, it usually settles quite well with massage. Triamcinolone also may be injected into the scar.<sup>23</sup>

Surgical failure may result from closure of the DCR anastomosis,<sup>24</sup> or an obstruction may occur at the common canaliculus, either undiagnosed preoperatively or developing postoperatively. Mucosal inflammation and subsequent scar tissue is the main cause of DCR failure, hence antimetabolites such as mitomycin-C (MMC) have been recommended, but studies show no conclusive advantage. Careful delicate surgery with correct placement of the ostium, respect for the mucosa, and avoiding any residual tissue or bony fragments facing the ostium is probably more important than adding antimetabolite.

Endoscopic revision of a simple inflammatory membrane can be done using a probe and fine blade, which often produces a permanent cure. In some situations, more extensive probing with placement of bicanalicular Silastic tubes may be useful to prevent granulation tissue from closing over the newly formed DCR opening.<sup>25</sup> If these smaller measures fail, a redo of external approach DCR with revision of flaps may be performed, and a bicanalicular Silastic stent tube is left in place for a minimum of 3 months. Using the endoscope simultaneously helps provide internal illumination and helps to confirm full new anastomosis. The success rate of this last procedure is greater than 80%.

If the obstruction is at the common canalicular level, a canaliculodacryocystorhinostomy (CDCR) may be useful. The scar tissue at the common canaliculus is excised; then the individual canaliculi or residual common canaliculus can be sutured into the nose.<sup>26</sup>

**Fig. 12.12.9 External Dacryocystorhinostomy.** (A) Posterior flaps of the sac and nasal mucosa being sutured. (B) Anterior flaps of the sac and nasal mucosa being anastomosed. (Adapted with permission from Hurwitz JJ. *Diseases of the sac and duct*. In: Hurwitz JJ, editor. *The lacrimal system*. Philadelphia, PA: Lippincott-Raven; 1996. Artwork courtesy Terry Tarrant, London.)

Even without suturing, a good result can often be obtained if a wide bony opening is made and silicone tubes placed for 4 to 6 weeks.

## Endonasal Dacryocystorhinostomy

When the obstruction is in the lower drainage system (below the lacrimal sac) and the canaliculi are anatomically normal, an endonasal approach is a good alternative to an external DCR; this will avoid cutaneous incisions and risk of scar.<sup>27-29</sup>

Endonasal endoscopy has a success rate reported to be equal to or slightly lower than the external approach.<sup>29,30</sup> However, the success rate can be improved by combining the external and endoscopic approach. After the nasal mucosa is decongested, a light pipe is passed through the canaliculus to the lacrimal bone and visualized in the nose. Many surgeons have abandoned using the light pipe as they become more experienced in endonasal lacrimal surgery, arguing that the light pipe risks damaging the canaliculi.

The nasal mucosa is incised, elevated, and reflected away from the opening with the use of a scalpel or fine blade.<sup>31</sup> The thin bone of the

lacrimal bone is removed and enlarged with Kerrison punches or a mechanical diamond bur.<sup>32</sup> The ostium should not extend behind the posterior lacrimal crest or above the lacrimal sac. The sac mucosa is opened with Vannas scissors or fine blade, and a portion of the medial wall of the sac is excised if it is a large sac. Silicone stents are placed through the system and left for 3 to 4 weeks. The endonasal approach also allows the surgeon to deal with nasal adhesions, granulation tissue, and hypertrophic turbinates at the same time. Endonasally the options are to use a nasal endoscope or a microscope for visualisation.

## TUMORS OF THE LACRIMAL SAC

Primary lacrimal sac tumors are rare and present as masses at the medial canthus. Depending on the age of the patient, there may or may not be symptoms of tearing. These patients often exhibit patency to syringing because the tumor usually arises in the epithelium and only later grows toward the lumen. Bloody tears may be present. Lacrimal sac tumors may be benign or malignant, epithelial or nonepithelial.<sup>33</sup> DCG and CT are useful to demonstrate the location of the mass and its extent and associated involvement of the lacrimal drainage pathways. Bony erosion is often present in these cases.

## DISEASES OF THE CANALICULI

Canalicular obstruction may have inflammatory, traumatic, idiopathic (topical or systemic drug related), or suppurative (canaliculitis—usually actinomycotic) causes. Whereas some diseases certainly involve both the punctum and the canaliculus (such as chronic staphylococcal lid margin disease), many involve either one or the other and so should be considered separately.<sup>34</sup>

## PUNCTAL STENOSIS

Punctal stenosis can be congenital or acquired.<sup>35</sup> Congenital obstruction may be caused by a membrane overlying the punctal papilla. In such situations, the rest of the punctum and the canaliculus are patent, so merely perforating the membrane with a No. 25 needle may be sufficient to achieve permanent patency. If the papilla of the punctum is absent, the distal canaliculus often has not developed either, so affected patients usually require the placement of a Jones tube. Marsupialization of the remaining canaliculus into the lacrimal lake does not offer a good solution. A Jones tube is done as part of—or secondarily after—a conjunctivo-DCR.

Acquired punctal obstructions may result from antiviral or antiglaucoma medications, cicatrizing diseases of the conjunctiva, various infections, radiation, and chemotherapeutic agents, which may also obstruct the canaliculi.<sup>36</sup> Intrinsic tumors, such as papillomas and skin malignancies (e.g., basal cell and squamous carcinoma), also may obstruct the puncta. Most acquired punctal obstructions, however, are secondary to punctal eversion, which may be related to eyelid laxity or to cicatrizing diseases of the skin.

## USEFUL LACRIMAL TIPS

- Take a good history of the watering eye/sticky eye/inflamed swelling at the corner of the nose.
- Watering eyes can be caused by eyelid or tear duct disease. Therefore examine both clinically, with dye tests, syringing, nasal endoscopy, and/or radiological imaging, to determine the cause and plan the treatment or surgery.
- Both external and endoscopic approach DCR give comparable good surgical results. Silicone intubation is being used less, for a shorter period, or not at all.
- A Jones tube is placed if there is a complete blockage of the canaliculi or their loss, for instance following a medial canthal tumour excision.

# Thyroid Eye Disease

Peter J. Dolman

# 12.13

**Definition:** Thyroid eye disease (TED) is an inflammatory orbital disease associated with autoimmune thyroid disorders that causes expansion and fibrosis of orbital fat and striated muscle, resulting in cosmetic and functional morbidity.

## Key Features

- Graves' disease is the most common autoimmune disorder.
- Approximately 50% of patients with Graves' disease may develop orbitopathy.
- The orbital target of the immune response is likely the pluripotential orbital fibrocyte.
- The most important clinical features of the orbitopathy are eyelid retraction, proptosis, restrictive strabismus, and dysthyroid optic neuropathy.
- Management is medical during the active inflammatory phase and surgical during the chronic fibrotic phase.

## INTRODUCTION

Thyroid eye disease (TED) is an orbital inflammatory disorder that is associated with thyroid autoimmune diseases and causes expansion and scarring of orbital fat and striated muscle.<sup>1,2</sup>

Although it is self-limited, TED may significantly disrupt cosmesis, vision, and quality of life.<sup>3</sup>

## EPIDEMIOLOGY, RISK FACTORS, AND ASSOCIATED CONDITIONS

TED is the most common orbital disease globally, with a prevalence estimated between 0.5%–2%, and with females outnumbering males by 4:1. It is most common between the second and sixth decade and occurs in all races.<sup>4,5</sup>

Risk factors for developing TED include a positive family history, smoking, life stressors, and poorly controlled hypothyroidism following radioactive iodine.<sup>6</sup> Predictors for more serious involvement by TED

include male gender, increasing age, smoking, and a rapid onset of orbitopathy.<sup>7</sup>

Cigarette smoking is strongly correlated with both the development of TED and with its severity.<sup>8</sup>

Patients with TED have an increased probability of developing associated immune diseases, including superior limbic keratitis (SLK), myasthenia gravis, diabetes mellitus, alopecia, and vitiligo.<sup>9</sup>

## PATHOGENESIS

TED often occurs in conjunction with autoimmune thyroid diseases such as Graves' disease (90%) or Hashimoto thyroiditis (3%); 90% of patients with orbitopathy have a current or past history of abnormal systemic thyroid hormone levels, whereas others may develop abnormal levels in the future.

In Graves' disease, an aberrant population of lymphocytes produce thyrotropin-receptor antibodies (TRAB), also known as thyroid-stimulating hormone receptor (TSH-R) antibodies.<sup>1</sup> Differing subtypes may cause more, less, or unchanged levels of serum thyroxine.

Similar receptor sites on skin and orbital fat and muscle fibrocytes also may be targeted by these autoantibodies in Graves' disease, resulting in orbitopathy in 50% and dermopathy (pretibial myxedema or acropachy) in 5%–10%.<sup>10</sup>

The target cell in TED is the pluripotential orbital fibrocyte, present both in orbital fat and striated muscle.<sup>11</sup> Binding of circulating TRAB to fibrocyte receptors induces adipogenesis and hyaluronic acid production, resulting in expansion and remodeling of orbital tissues. The process is enhanced by the release of cytokines by T-helper cells, potentiated by binding of adjacent insulin-growth factor receptors (IGF-1) (Fig. 12.13.1).<sup>1,12,13</sup>

## CLINICAL PRESENTATION: DISEASE SEVERITY AND ACTIVITY

TED presents with a spectrum of clinical features determined by which orbital tissues are involved. The pattern and extent of involvement are graded as "disease severity."

Approximately two-thirds of TED patients develop primarily fat expansion, often in association with focal levator muscle inflammation, resulting

**Fig. 12.13.1 Binding of Autoantibodies to TSH Receptors on Fibroblasts Leads to Activation of T-Helper Cells, Secretion of Inflammatory Cytokines, and Production of Hyaluronan.** Some of the pluripotential fibrocytes differentiate into adipocytes following binding to TSH receptor antibodies. Binding of IGF-1 to nearby IGF-1 receptors may synergistically enhance TSH receptor signaling, hyaluronan production, and adipogenesis. The resulting connective tissue remodeling produces the varying degrees of extraocular muscle enlargement and orbital fat expansion characteristic of TED. (Reprinted from Bahn RS and Kazim M. Thyroid. In: Fay A, Dolman PJ, editors. Diseases and disorders of the orbit and ocular adnexa. Elsevier; 2016. p. 223.)

**Fig. 12.13.2** (A) Young female demonstrates proptosis and bilateral upper lid retraction with lateral flare. (B) Axial computerized tomography (CT) scan of same patient shows marked proptosis from fat expansion but minimal muscle enlargement. (Courtesy Fay A, Dolman PJ, editors. *Diseases and disorders of the orbit and ocular adnexa*. Elsevier; 2016. p. 220.)

in eyelid retraction, proptosis, and ocular exposure. This pattern typically evolves very slowly in a younger, predominantly female population (Fig. 12.13.2).<sup>2</sup>

The remaining third have significant enlargement of one or more extraocular muscles and present with more severe features, including congestion and edema of the conjunctiva and eyelids, restricted ocular ductions with diplopia, and dysthyroid optic neuropathy (DON), resulting from apical compression of the optic nerve by the swollen muscles. Muscle-centric disease usually develops more rapidly in an older population with a more balanced gender distribution and is more likely to be associated with smoking and a positive family history of TED (Fig. 12.13.3).<sup>7,14</sup>

TED has a biphasic course, with a progressive (“active”) phase lasting 6–18 months, followed by a stable (“inactive”) phase.<sup>15</sup> These disease phases are graded as “clinical activity.” “Rundle’s curve” is a graph of orbital disease severity against time (Fig. 12.13.4), with a steeper slope in the progressive phase reflecting more aggressive disease.<sup>7</sup> Immunomodulators and radiotherapy administered during the early active phase may limit the destructive consequences of the immune cascade. Surgery is usually performed in the postinflammatory phase for orbital cosmesis, comfort, and function but may be needed during the progressive phase to prevent vision loss from DON or corneal breakdown.<sup>16</sup>

Recurrence of TED occurs in less than 10% of cases.<sup>17</sup>

## DIAGNOSIS

Diagnosis of TED is based on three aspects of the disease:

(i) **Clinical Features:** Characteristic findings such as lid retraction combined with proptosis and limited motility are highly suggestive of TED, particularly when bilateral.

(ii) **Thyroid Function and Antibody Tests:** Abnormal thyroid function tests (thyroxine and TSH levels) or a history of thyroid dysfunction help confirm the diagnosis, although 10% of TED patients may be euthyroid at onset. The presence of TSH-R antibodies has high sensitivity for active Graves’ disease.<sup>18</sup>

(iii) **Orbital Imaging:** Computerized tomography (CT), magnetic resonance imaging (MRI), or ultrasound may help confirm the diagnosis, particularly

**Fig. 12.13.3** (A) Older male shows periorbital soft tissue congestion associated with restricted ocular movements and dysthyroid optic neuropathy (DON). (B) Axial CT scan of same patient shows enlargement of muscles with proptosis and apical crowding. (Courtesy Dolman PJ. *Assessment and management plan for Graves’ orbitopathy*. In: Bahn RS, editor. *Graves’ disease: a comprehensive guide for clinicians*. New York: Springer; 2015.)

**Fig. 12.13.4** Rundle Curve Plots Disease Severity (y-axis) vs Time (x-axis), With an Active, Progressive Phase Followed by an Inactive, Stable Phase. Medical or radiotherapy are offered during the progressive phase to reduce the severity of the orbital changes. Surgical reconstruction is typically performed once the disease is quiescent.

for atypical or uncertain clinical situations. The CT scan documents fat or muscle enlargement and apical crowding and allows assessment of bony walls and sinuses for possible surgical decompression. Contrast CT scans may show enhancement of the extraocular muscle sheaths or stranding of surrounding orbital fat in the active inflammatory phase<sup>2</sup> or reduced

enhancement and lucent spaces in the extraocular muscles in the inactive phase. MRI identifies edema within the extraocular muscles on T2 or STIR sequence in active disease.<sup>19,20</sup>

EVALUATION OF DISEASE SEVERITY AND ACTIVITY

Early diagnosis permits an accurate evaluation of TED, including assessment of disease severity and activity and identification of those individuals at high risk of developing more serious complications.

(i) **Disease Severity:** Werner's NO SPECS Classification grades specific clinical features of TED and assigns a global severity score (Table 12.13.1).<sup>21</sup> This highlights the different manifestations of the disease in order of frequency of presentation, but the descriptors for each grade focus on only one aspect while summary scores hide details about how the patient is specifically affected. Werner's scale does not assess clinical activity nor provide a means for defining management.<sup>2</sup>

The European Group on Graves' Orbitopathy (EUGOGO) TED severity scale is based on three management categories.<sup>22</sup> "Mild disease" includes lid retraction, mild proptosis, and minimal muscle involvement and is usually treated conservatively. "Moderate to severe disease" incorporates individuals with greater proptosis, inflammation, or motility restriction interfering with ability to function and is often treated medically. "Very serious disease" refers to sight-threatening conditions such as DON or corneal ulceration and may necessitate urgent surgical intervention. In this system, the distinction between mild and moderate disease is imprecise, and the moderate class is a broad, heterogeneous category, including individuals with soft tissue congestion, motility disturbances, and severe proptosis.<sup>2</sup>

(ii) **Disease Activity:** Determination of activity in cases with primarily fat expansion and an indolent course may be challenging, but these cases often are referred in a stable phase when surgery can be offered on a nonurgent basis. Cases with significant muscle involvement have a more obvious progression through the active and postinflammatory inactive phases, with congestive and inflammatory periocular changes usually developing from expanding ocular muscles, alerting the clinician that the disease is progressive and may lead to significant visual impairment from diplopia or DON.

BOX 12.13.1 Clinical Activity Score (CAS)

For initial CAS, only score items 1–7

1. Spontaneous orbital pain.
  2. Gaze evoked orbital pain.
  3. Eyelid swelling that is considered to be due to active (inflammatory phase) Graves' orbitopathy (GO).
  4. Eyelid erythema.
  5. Conjunctival redness that is considered to be due to active (inflammatory phase) GO.
  6. Chemosis.
  7. Inflammation of caruncle or plica.
- Patients assessed after follow-up between 1 and 3 months can be scored out of 10 by including items 8–10.
8. Increase of >2 mm in proptosis.
  9. Decrease in uniocular excursion in any field of gaze >8°.
  10. Decrease in visual acuity of >1 line on Snellen chart.

The affected patient may report the date and rate of disease onset as well as the recent disease course, even on the first visit.<sup>2</sup>

The *Clinical Activity Score (CAS)* is a global scale of soft tissue inflammation designed to identify active TED patients who might benefit from immunosuppressive therapy<sup>23</sup> (Box 12.13.1). It uses a binary scale to assess seven periocular soft tissue inflammatory/congestive features as surrogate markers of disease activity. On follow-up visits, additional points are given for increased proptosis (2 mm or more), decreased ocular motility (8° or more), or decreased visual acuity over the previous 3 months. A CAS score of 4 or higher has an 80% positive predictive value and a 64% negative predictive value for response to corticosteroid therapy. However, it has not been proven to correlate with risk of developing significant complications such as diplopia or DON. It is limited by significant false-positive and -negative cases. DON may develop in the context of low CAS values, patients with fat-centered disease may develop dramatic proptosis and lid retraction without any soft-tissue inflammatory changes, and some individuals with high CAS may have long-standing congestive changes that are unresponsive to any immunotherapy but respond best to mechanical surgical decompression.<sup>2</sup>

Lastly, both laboratory studies (urine and serum glycosaminoglycans and TSH-R antibodies) and imaging techniques (contrast-enhanced CT, T2/STIR sequence MRI, octreotide scans, and facial thermography) have been used to quantify activity, but none have proven more reliable than clinical assessment of disease progression.<sup>24</sup>

(iii) **VISA Classification:** This recording form grades both disease severity and activity using subjective and objective inputs.<sup>25</sup> It clusters the clinical features of TED into four discrete parameters: V (vision, DON); I (inflammation, congestion); S (strabismus, motility restriction); A (appearance, exposure).

The standard visit form (Fig. 12.13.5) is divided into four sections recording specific symptoms on the left and validated signs for each eye on the right. After each section is a progress row (better, same, worse) documenting the impression of both patient and clinician of the change in that parameter since the previous visit. Progress is documented on the basis of defined interval changes (i.e., 2 mm change in proptosis, 12° change in ocular ductions) rather than on global scores.

The layout follows the usual sequence of the eye examination and facilitates comparison of measurements between visits as well as data collation for research.

Summary grades for the severity and progress for each of the four disease parameters are documented at the bottom of the form. Unlike the EUGOGO scale that rates severity based on the presence of specific TED measurements, the VISA classification grades the severity and activity of each parameter independently.

Activity is determined by a defined interval deterioration in any one of the four parameters. The VISA I-score (for inflammation/congestion) assesses periocular soft tissue congestive features in a similar manner to CAS but uses a more sensitive 0–2 score for chemosis and eyelid edema. However, the CAS defines active disease on the basis of an absolute score >4, whereas VISA defines activity on the basis of a deterioration in I-scores (>2) or a specified progression in any of the other VISA parameters.

On the first visit, the date and rate of onset and historic progress of both the systemic and orbital symptoms are recorded, defining characteristics of the disease course. Additional questions also determine risk

factors for more serious TED outcomes associated with extraocular muscle involvement, including smoking, family history, and diabetes. A first-visit form (2 pages) and follow-up form (1 page) may be downloaded from the International Thyroid Eye Disease Society (ITEDS) website: <http://thyroideyedisease.org/>.

## QUALITY OF LIFE

Although objective measurements document disease severity, and interval changes document disease activity, subjective measurements of quality of life are also important to gauge the disease. The European Graves' Ophthalmopathy Quality of Life questionnaire (GO-QOL) consists of 16 questions, half pertaining to visual functioning and half to appearance.<sup>26</sup> The Graves' Ophthalmopathy Quality of Life Scale (GO-QLS) consists of a single question about overall well-being, a single question about appearance, and seven questions about visual function. The Thyroid Eye Disease Quality of Life scale (TED-QOL) is a simple three-item questionnaire with a 10-point Likert scale relating to satisfaction with overall quality of life, ability to function, and appearance. The latter is simple to administer and score and is designed to function both as a research tool and a simple office questionnaire.<sup>27,28</sup>

## BASIC MANAGEMENT

Management of TED is ideally performed using a multidisciplinary team, each with an area of expertise. The endocrinologist manages the thyroid status, the ophthalmologist the orbital disease, a rheumatologist prescribes immunomodulators, the radiation oncologist plans radiotherapy, and a surgeon may perform thyroidectomies.

The patient and their family should be taught the natural history of the disease, the role of the immune system, and how management varies depending on the disease phase. Young patients with fat-targeted indolent disease can be reassured they are unlikely to develop serious complications, whereas high-risk individuals with rapid onset of more muscle-targeted disease should be advised about potential complications and that it may take up to 2 years until the disease is quiescent and restorative surgery performed.

Supportive measures, such as cool compresses and head elevation for periorbital congestion and lubricants for exposure, should be offered to all patients.

## MEDICAL THERAPY

**(i) Gluco-corticosteroids (CS):** These remain the first choice for active TED with significant inflammatory signs. They may reverse DON, although this may be incomplete or temporary so that adjunctive radiotherapy or surgical decompression may be necessary. They also are recommended preventively to avoid exacerbation of active TED at time of radioactive iodine thyroid ablation.<sup>29</sup>

Standard oral therapy is daily prednisone 0.5–1.0 mg/kg daily for 6 weeks, but this route has side effects in 50% of cases, including Cushing's syndrome, diabetes mellitus, insomnia, mood disturbances, gastric ulcers, osteopenia, necrosis of the femoral head, and susceptibility to infections.<sup>30</sup>

Intravenous CS therapy reduces the incidence of side effects and allows a longer duration of therapy.<sup>31</sup> A popular protocol is IV methylprednisolone 500 mg weekly for 6 weeks, reducing to 250 mg weekly for 6 weeks. The author prefers to titrate the dose or prolong the intervals depending on clinical response. Liver failure and rare cases of death have been reported in cumulative doses over 8 g of methylprednisolone.<sup>32</sup>

Depot CS injection into the inferolateral orbital fat pocket is beneficial for focal orbital congestion<sup>33</sup> but carries a small risk of intravascular emboli with visual loss.

Retrospective studies find efficacy of 60% overall for oral CS and 85% for IV CS in reducing inflammatory features in active TED.<sup>34</sup> The effect occurs within 24 hours but is short lived, so prolonged therapy is required (Fig. 12.13.6). A recent large series from Vancouver found that although appropriate doses of CS effectively reduced inflammatory scores, 17% of patients in the high-risk muscle-targeted group developed DON and 35% had worsening of diplopia or ocular restriction. In a comparable group in which combined CS and radiotherapy was provided, none developed DON, and improved diplopia and motility scores were observed.<sup>35</sup>

**(ii) Nonsteroidal Immunotherapy:** Cyclosporine combined with CS enhances its benefit against inflammatory soft tissue changes.<sup>36</sup>

**Fig. 12.13.6** (A) 47-year-old female with recent onset of inflammatory changes (CAS score 7/10, VISA inflammatory score 9/10). The history of progression indicates active disease, and the congestive changes indicate extraocular muscle enlargement (and the risk for serious sequelae) based on the VISA classification criteria. (B) She was treated with corticosteroid for control of the inflammatory changes and later with radiotherapy to prevent onset of motility disruption and optic neuropathy. The inflammatory soft tissue changes resolve in response to corticosteroids and radiotherapy, but the upper lids remain retracted, suggesting levator scarring has already occurred. (Courtesy Dolman PJ. Assessment and management plan for Graves' orbitopathy. In: Bahn RS, editor. Graves' disease: a comprehensive guide for clinicians. New York: Springer; 2015.)

Intravenous immunoglobulin (IVIg) therapy is reported to be as effective as oral GC with a low rate of adverse effects but is prohibitively expensive.<sup>37</sup>

**(iii) Rituximab (RTX):** This anti-CD20 chimeric monoclonal antibody induces transient B-cell depletion and blocks early B-cell and T-cell activation.<sup>38</sup> Small case series have found benefit in reducing CAS scores in cases refractory to CS. Two recent randomized controlled trials have studied the use of rituximab for moderately severe, active TED. The Mayo Clinic study randomized 25 participants into infusions of either RTX or saline.<sup>38</sup> Both groups improved over a year follow-up with no significant difference noted between CAS or QOL scores. A study by Salvi et al. ( $n = 32$ ) found RTX given either as two biweekly 1000-mg infusions or as a single 500-mg infusion was better at reducing CAS scores compared with IVCS (methylprednisolone 7.5 g total).<sup>39</sup> The inactivation rate (defined as a reduction of CAS to 3) at 24 weeks was 100% in the RTX group and 69% in the IVCS group ( $P < 0.04$ ).

**(iv) Tocilizumab:** A prospective study on a series of 18 active TED patients resistant to IVCS found significant benefit in terms of proptosis, CAS, and strabismus reduction using tocilizumab, a humanized monoclonal antibody against the interleukin-6 receptor.<sup>40</sup> A randomized double-blind

prospective trial is now being conducted to confirm these promising findings. This drug is administered intravenously monthly until disease control with significant side effects including gastrointestinal ulcers and respiratory infections in up to 10% of individuals. A subcutaneous delivery system may have fewer complications.

(v) **Selenium** is an oral antioxidant mineral found in Brazil nuts, tuna, and dark green leafy vegetables. A EUGOGO randomized controlled study in patients with mild TED found greater improvement in lid retraction, CAS, and QOL scores in those supplemented with selenium 100 µg twice daily compared with a placebo group after 6 months of therapy and 6 months after cessation of the drug. No adverse effects were identified.<sup>41</sup> This study was conducted in countries with selenium-deficient diets, so a follow-up study is planned by ITEDS for North America, where selenium dietary levels are adequate.

## ORBITAL RADIOTHERAPY

(i) **Mechanism:** External beam radiotherapy (RT) has been used for TED for more than 60 years and is thought to work by inhibiting or depleting lymphocytes and fibroblasts in the involved orbital tissue. Typically 20 Gy (2000 Rads) divided over 10 days are delivered to the retrobulbar orbit through a lateral port, avoiding ocular or intracranial exposure.<sup>42</sup>

### (ii) Indications:

V: DON: The addition of RT to CS was shown to reduce the incidence of developing DON in high-risk progressive TED from 17% (CS alone) to 0% (CS and RT).<sup>35</sup> In patients with established DON, the addition of RT to CS was shown to reduce the need for decompression surgery compared with CS treatment alone.<sup>43</sup> RT may also be useful in preventing progressive expansion of muscles and recurrence of vision loss following successful orbital decompression.<sup>42</sup>

I: Inflammation/congestion: RT reduces periocular inflammation in 60% of patients with active TED, similar to the success rate for oral CS.<sup>44</sup> The benefit of prednisone tends to be more rapid, whereas for RT it is longer lasting. Prednisone combined with RT has greater benefit than treatment with prednisone alone.<sup>45</sup>

S: Strabismus/motility: Two randomized controlled studies from the Netherlands found that patients with TED treated with RT ultimately had better ocular excursions than patients treated with sham (no) RT.<sup>46,47</sup>

A: Appearance/exposure: Radiotherapy has little benefit in reducing ultimate proptosis or lid retraction.

RT is most effective for active (progressive) disease and is unlikely to reverse orbital changes in stable, postinflammatory thyroid eye disease.<sup>48</sup>

(iii) **Safety and Complications:** Modern linear accelerator radiotherapy units have an excellent safety record with retrospective series in TED showing no increased risk of cataract and no reports of radiation induced tumors.<sup>49</sup> Because of a small theoretical lifetime risk of developing tumors, its use for TED is contraindicated in people younger than 35 years.<sup>37</sup>

RT may increase the incidence of retinal vascular disease in patients with diabetes mellitus (DM) or hypertension, and its use is often avoided in patients with DM.

Radiotherapy may cause some temporary redness and hair loss in the temple area near where the beam is focused. Orbital inflammation may increase during RT, but this can be controlled with concurrent oral CS.

## SURGICAL THERAPY

(i) **Timing of surgery:** Surgical rehabilitation for TED is considered during the inactive phase following several months of stable measurements and controlled thyroid status (see Fig. 12.13.4). Surgery may be necessary during the active phase when vision is threatened and may include orbital decompression for refractory DON or tarsorrhaphy and lid-narrowing procedures for corneal breakdown from prominence of the eyes or severe lid retraction.

Surgery for TED is staged sequentially: 1. Orbital decompression; 2. Strabismus repair; and 3. Eyelid retraction surgery and blepharoplasties.

(ii) **Orbital Decompression:** This is used for dysthyroid optic neuropathy, proptosis, and chronic orbital congestion. The surgery involves a combination of bone wall removal and resection of orbital fat.

Decompression involves bone wall and/or fat removal, depending on the indication, the targeted tissue, and the desired amount of proptosis reduction.

Optic nerve apical compression by expanded extraocular muscle is relieved by out-fracture of the medial orbital wall into the posterior ethmoid sinus and the medial floor into the maxillary sinus (Fig. 12.13.7). Even significant or longstanding vision loss may be reversed by an effective decompression. Adjunctive CS or RT may be offered to avoid postoperative

**Fig. 12.13.7** (A) Coronal CT scan showing left orbital apex optic nerve crowding from enlarged extraocular muscles. Little perineural fat is visible, and Snellen visual acuity was reduced to 6/60 in the left eye. (B) Postoperative coronal CT scan demonstrates medial wall decompression relieving pressure on optic nerve. Vision was restored to 6/6. Notice that the medial rectus muscle continued to expand following the decompression, and this may be reduced with concomitant radiotherapy. (Courtesy Dolman PJ. Evaluating graves orbitopathy. *Best Pract Res Clin Endocrinol Metab* 2012;26:229–48. p. 240.)

deterioration in vision, because the disease is typically in an active stage with progressive muscle expansion.<sup>42</sup>

The most common indication for decompression is proptosis reduction during the inactive phase to improve comfort and appearance (Fig. 12.13.8). A swinging eyelid approach allows access to the lateral wall, floor, and medial wall, and any combination of bone wall removal and fat removal may be chosen, depending on the relative contribution of fat versus muscle tissue expansion. Specific complications are associated with each of the walls removed. Cheek numbness and globe inferior displacement may occur with floor decompression, oscillopsia may occur with lateral rectus/temporalis muscle apposition following lateral wall decompression,<sup>50</sup> and sinusitis and ethmoidal nerve anesthesia may arise following medial wall decompression.

A rare indication for decompression is relief of long-standing soft tissue congestion. These individuals may have high CAS/VISA inflammatory scores, but the disease is inactive with no change in VISA grades and no response to CS. Improved venous drainage following expansion of the orbital compartment often results in a gratifying and immediate improvement in congestion and inflammatory scores (Fig. 12.13.9).

Strabismus is a troublesome consequence of decompression surgery. This is particularly common in cases with enlarged extraocular muscles and pre-existing strabismus, often seen in cases of optic neuropathy or chronic congestion. It occurs in less than 10% of cases of fat-targeted disease, regardless of the approach or technique.

(iii) **Strabismus Surgery:** Individuals with muscle-targeted progressive TED have a significant risk of developing muscle scarring, restriction, and strabismus with significant impact on QOL.

**Fig. 12.13.8** (A) Asymmetrical right proptosis with upper and lower eyelid retraction. (B) Orbital CT scan demonstrating right axial proptosis with muscle and fat enlargement. (C) Same patient following right orbital decompression, right upper lid lowering and lower lid elevation. (Courtesy Dolman PJ. *Evaluating Graves' orbitopathy*. *Best Pract Res Clin Endocrinol Metab* 2012;26:229–48. p. 235.)

At the first symptoms of diplopia, combined radiotherapy and corticosteroid therapy might limit progression and preserve the greatest field of single binocular vision.

Strabismus and ductions can be assessed both in the office and by an orthoptist so that a temporary prism can be fitted and measurements repeated until stable for at least 6 months, when surgery may be offered. The orthoptist also measures fusional amplitudes and torsion to assist in surgical planning.

**Fig. 12.13.9** (A) 62-year-old female with a high VISA inflammatory score based on her soft tissue changes. However, she had been referred on combination oral corticosteroids and cyclosporine for over a year with no history of progression, and was *inactive* following the VISA classification guideline (although her CAS score would have been interpreted as active). (B) One month following bilateral orbital decompression and upper lid lowering, her congestive features had resolved and her medications were tapered off. Both the VISA inflammatory score and CAS scores were reduced to zero. (Courtesy Dolman PJ. *Assessment and management plan for Graves' orbitopathy*. In: Bahn RS, editor. *Graves' disease: a comprehensive guide for clinicians*. New York: Springer; 2015.)

Most strabismus surgery for TED consists of recessions, often on adjustable sutures (Fig. 12.13.10). Inferior rectus recessions are prone to slippage, which might be mitigated by use of nonabsorbable sutures and undercorrecting slightly.<sup>51</sup>

Inferior rectus recessions may induce a secondary lower lid retraction, necessitating subsequent lower lid spacer grafts.

**(iv) Eyelid Surgery:** Upper eyelid retraction is associated with enlargement and scarring of the levator complex and is treated with recession of the scarred complex (Fig. 12.13.11).<sup>52</sup> Lower eyelid retraction is mostly associated with proptosis, although secondary retraction from inferior rectus recession is well recognized. Orbital decompression with floor removal may actually accentuate upper lid retraction (as the upper lid remains tethered while the globe is relatively lowered), whereas lower lid retraction may be reduced.

In progressive disease, retraction is usually managed conservatively with topical lubricants unless the cornea is threatened, in which case a temporary tarsorrhaphy or levator release may be performed.

## MANAGEMENT PLAN USING THE VISA CLASSIFICATION

The VISA classification organizes the four disease parameters in order of descending priority for management.

**Fig. 12.13.10** (A) 45-year-old female with progressive disease with bilateral upgaze restriction, constant diplopia, and upper lid retraction. (B) Quiescent disease following combined IV corticosteroids and radiotherapy and subsequent ocular alignment surgery and upper lid lowering surgery. (Courtesy Dolman PJ. Assessment and management plan for Graves' orbitopathy. In: Bahn RS, editor. Graves' disease: a comprehensive guide for clinicians. New York: Springer; 2015.)

(i) **V: Vision:** DON is recognized by progressive color and central vision loss with inferior paracentral visual field defects and apical nerve crowding on coronal CT scans. Initial treatment includes systemic corticosteroids, administered either orally (1.5 mg/kg prednisone daily) or intravenously (1 g IV methylprednisolone on alternate days for a week). Incomplete restoration of vision or relapse on tapering of CS may necessitate orbital decompression, usually with excellent response.

Adjunctive external beam radiotherapy may reduce the need for surgical decompression and has been used following decompression to prevent continued postoperative expansion of muscle and recurrence of visual impairment.<sup>42</sup>

Rituximab may be useful in some cases of DON refractory to corticosteroids.<sup>53</sup>

(ii) **I: Inflammatory and congestive soft tissue changes:** These are scored using the VISA inflammatory score or CAS.

Cases with mild soft tissue inflammatory changes (low scores) are managed conservatively with cold compresses and head elevation. Cases with moderate scores can be given a trial of oral prednisone and assessed for improvement. Patients with high scores are typically treated with intravenous corticosteroids with good response on a short-term basis and radiotherapy for long-term effect. Because high inflammatory scores may reflect disease activity, close attention to signs of progress in the other VISA parameters is vital. Refractory cases may respond to combination therapy

**Fig. 12.13.11** (A) Right upper eyelid retraction with 3 mm scleral show and lateral flare. (B) Coronal CT scan of same patient showing corresponding enlargement of right levator palpebrae superioris muscle (asterisk). (Courtesy Dolman PJ. Assessment and management plan for Graves' orbitopathy. In: Bahn RS, editor. Graves' disease: a comprehensive guide for clinicians. New York: Springer; 2015.)

(including cyclosporine or newer monoclonal antibody biologic agents). In chronic nonprogressive cases refractory to medical therapy, surgical decompression often is beneficial.

(iii) **S: Strabismus and restricted motility:** Diplopia is treated with prisms or patching during the active phase, and systemic corticosteroids combined with orbital radiotherapy may limit restriction in ocular motility. Once a stable phase is documented, alignment surgery or permanent prisms are beneficial.

(iv) **A: Appearance and exposure changes:** These are treated with lubricant drops and patching during the active phase. Rarely, a tarsorrhaphy or an orbital decompression may be required for corneal breakdown or ulceration. Once the disease becomes inactive, surgery may reduce proptosis, eyelid retraction, and orbital fat prolapse.<sup>42</sup>

Orbital Infection and Inflammation

Alan A. McNab

12.14

**Definition:** Inflammation or infection of the orbital contents.

Key Features

- Clinical signs of orbital inflammation or infection include redness (eyelids and/or conjunctiva), swelling (proptosis, eyelid swelling and conjunctival chemosis), pain (not always present), and loss of function (reduced ocular motility, loss of vision).
- Every effort should be made to differentiate infection from noninfective inflammation and to establish the nature of any noninfectious inflammation (by appropriate investigation often with tissue biopsy).

INTRODUCTION

Infections or noninfectious inflammations are probably the most common orbital conditions encountered in clinical practice. The most common inflammatory orbital condition, Graves’ orbitopathy, is covered in a separate chapter (see Chapter 12.13).

The cardinal features of acute inflammation (redness, heat, pain, swelling, and loss of function) are seen in many of the conditions covered in this chapter but not all. Noninfectious orbital inflammations are often sub-acute or chronic and may have few signs of inflammation.

GENERAL ASSESSMENT

When assessing a patient with possible orbital infection or inflammation, the first and most important step is to obtain an accurate and thorough clinical history. This will include time and rapidity of onset of symptoms, a systematic review of ocular and orbital symptoms, and a full general medical history, as orbital inflammations are often associated with systemic diseases.

A complete examination of the eyes and orbits, the nasal cavity, and regional lymph nodes and salivary glands should be performed.

First-line imaging is usually a computed tomography (CT) scan. This will be adequate in most circumstances. An orbital magnetic resonance imaging (MRI) scan may provide additional information in some patients.

Material for microbiological examination should be sought for suspected bacterial orbital cellulitis. Conjunctival swabs are rarely helpful. Pus obtained from the ostia of infected sinuses or abscess cavities is most useful. Blood cultures are rarely positive<sup>1</sup> but may be helpful in an acutely ill, febrile patient.

In practice, it is often unclear whether a patient has an infectious or noninfectious orbital inflammation, and a trial of antibiotics is reasonable. If there is no response, investigations should be directed toward establishing a specific cause for the inflammation. Blind treatment with corticosteroids or other anti-inflammatory medications should be avoided, as this will often cloud or delay the diagnosis.

For patients with suspected noninfectious orbital inflammation, blood tests may help establish a diagnosis.<sup>2,3</sup> The usual panel of blood tests and imaging are listed in Table 12.14.1.

For patients with noninfectious orbital inflammation, tissue for histopathological examination should be obtained if possible. Many specific forms of inflammation cannot be diagnosed without a biopsy. Exceptions might include a patient with a typical presentation of orbital myositis or orbital apical inflammation.

Orbital Infection

Orbital infection is most commonly bacterial (orbital cellulitis), but viral, fungal, and parasitical infections may occur (Table 12.14.2).

Orbital Cellulitis

Bacterial infection of the orbital tissues (orbital cellulitis) is the most common orbital infection, and untreated it can lead to blindness and spread of infection to the cranial cavity. It is important to distinguish between preseptal (eyelid) cellulitis and the more dangerous orbital cellulitis. Orbital cellulitis, in addition to signs of eyelid inflammation (redness and swelling), will have signs of orbital inflammation—conjunctival redness and swelling (chemosis), proptosis, and potentially loss of function (visual loss and reduced eye motility) (Fig. 12.14.1).

The most common source of infection in orbital cellulitis is paranasal sinusitis complicating upper respiratory tract infection.<sup>1</sup> Bacterial overgrowth in the sinuses spreads to the adjacent orbit. Other much less common sources are spread from the globe (panophthalmitis), the eyelids, the lacrimal sac, infected teeth, and orbital foreign bodies.

Abscesses may form, either in the subperiosteal space or within the orbital tissues. The most common site is the medial subperiosteal space adjacent to the ethmoid sinuses. (Fig. 12.14.2A) In children, these medial subperiosteal collections may be sterile.<sup>4,5</sup>

All patients with orbital cellulitis should be admitted to the hospital for careful observation and documentation of clinical signs, including visual

Serum IgG and IgG4 levels
Orbital CT scan (first line) and/or MRI
Chest x-ray or CT scan of chest (sarcoidosis)

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; FBC, full blood count.

TABLE 12.14.2 Causes of Orbital Infection

1. Bacterial
  - orbital cellulitis
    - spread from adjacent structures
      - paranasal sinuses
      - eyelids
      - dental infections
      - panophthalmitis
    - orbital foreign bodies
    - hematogenous
    - tuberculosis
2. Viral
  - herpes zoster ophthalmicus
3. Fungal
  - mucormycosis
  - aspergillus
4. Parasitical
  - cysticercosis
  - echinococcosis (hydatids)

**Fig. 12.14.1** A Young Man With Severe Right Orbital Cellulitis. There is proptosis, chemosis, reduced ocular motility, and reduced vision.

**Fig. 12.14.2** (A) An axial orbital CT scan of an infant with a medial subperiosteal collection adjacent to opacified and underdeveloped ethmoid paranasal sinuses. (B) A coronal CT scan of a 14-year-old male with right orbital cellulitis and a superior subperiosteal abscess. There is pansinusitis, including frontal sinusitis. The location of the abscess and presence of frontal sinusitis are both indications for drainage of the abscess. (Harris GJ. Subperiosteal abscess of the orbit. Age as a factor in the bacteriology and response to treatment. *Ophthalmology* 1994;101:585–95. Garcia GH, Harris GJ. Criteria for non-surgical management of subperiosteal abscess of the orbit. *Ophthalmology* 2000;107:1454–8.)

function, and immediate intravenous antibiotics. The choice of antibiotic should be in consultation with local infectious diseases experts, but a common combination is ceftriaxone and flucloxacillin. Anaerobic cover may be required in older patients.

All patients should have a CT scan of the orbits and paranasal sinuses. If there is evidence of an orbital abscess, consideration should be given to urgent surgical drainage, especially with visual compromise or progression of clinical signs. In children 9 years of age or younger, most medial subperiosteal abscesses (SPAs) are sterile and often small. Provided vision is not compromised, they may be observed and most resolve without surgical intervention. Surgery should be performed if the abscess is elsewhere (see Fig. 12.14.2B), visual compromise exists, the SPA is large, frontal sinusitis is present (see Fig. 12.14.2B), or the collection has recurred after previous

**Fig. 12.14.3** (A) An adult male with redness, swelling, and pain over the left lacrimal gland due to bacterial dacryoadenitis. Note the S-shaped deformity of the upper eyelid. (B) There is redness and conjunctival chemosis laterally with purulent material visible in the palpebral lobe of the lacrimal gland.

drainage.<sup>4,5</sup> If an organism is found in this age group, it is usually a single aerobic bacterium.

For children over 15 years of age and adults, more complex infections are more common, with multiple organisms and often anaerobes as well. These patients should have any SPA or other abscess drained. Between ages 9 and 15, there is a transition, and a more active surgical role is often—but not always—required.

In recent years, antibiotic-resistant bacteria have become a more common cause of orbital infection. The most common is methicillin-resistant *Staphylococcus aureus* (MRSA). Orbital infection with MRSA usually occurs without antecedent upper respiratory tract infection or adjacent paranasal infection, abscess formation is commonly multiple, and the lacrimal gland is often involved.<sup>6</sup> Despite the emergence of these more aggressive and atypical infections, the guidelines established for management of subperiosteal collections remains valid.<sup>7</sup>

### Bacterial Dacryoadenitis

Suppurative dacryoadenitis, bacterial infection of the lacrimal gland, is an uncommon infection and a rare cause of lacrimal gland inflammation. Signs of inflammation are maximal over the lacrimal gland (Fig. 12.14.3A). Pus may be seen coming from lacrimal ductules (Fig. 12.14.3B), and should be sent for microbiological examination. Infection may spill over into the adjacent orbit. Abscesses may occasionally form and require drainage.<sup>8</sup>

### Orbital Tuberculosis

Orbital tuberculosis is rare, especially in the West. It occurs usually by hematogenous spread and can occur in several forms: periostitis, soft tissue tuberculoma (cold abscess) with or without bony involvement, or dacryoadenitis. It may also spread from adjacent paranasal sinuses.<sup>9</sup> Diagnosis depends on biopsy confirmation of caseating or necrotizing granulomatous inflammation with acid-fast bacilli seen, preferably with a positive tissue culture.

### Orbital Viral Infection

The only significant orbital viral infection is that due to herpes zoster ophthalmicus (HZO). In rare instances, an orbital apex syndrome can occur with multiple cranial nerve palsies and loss of vision. The orbit may also be more generally inflamed with proptosis.<sup>10,11</sup>

### Orbital Fungal Infection

Fungal infections of the orbit fall generally into two groups: acute, fulminant infection with fungi of the Mucorales family (rhino-orbital-cerebral mucormycosis), and invasive aspergillus infection, a more indolent infection.

#### Rhino-Orbital-Cerebral Mucormycosis

Mucormycosis usually occurs in the setting of one of the following: diabetes, usually with ketoacidosis, hematological malignancies with poor white cell function, and solid organ and bone marrow transplantation with immunosuppression. Altered iron metabolism is a risk factor that may also occur in diabetics.<sup>12,13</sup>

The fungus is saprophytic and invades the orbit from adjacent affected paranasal sinuses. The organism is angiotropic (invades blood vessels) and leads to tissue necrosis. Clinical signs progress rapidly, usually with ophthalmoplegia, proptosis, ptosis, and often a central retinal artery occlusion with optic neuropathy (Fig. 12.14A and B). Necrosis of tissues (eyelids, scalp, palate) can occur as a late sign. Changes on CT or MRI are often deceptively mild (Fig. 12.14C).

The prognosis for patients with mucormycosis is poor, and many die of cerebral involvement. Survival depends on a high index of suspicion, prompt diagnosis by obtaining tissue for histopathological examination (urgent) and culture, reversal of any factors such as ketoacidosis, antifungal agents, and soft tissue debridement, often in the form of orbital exenteration.

#### Orbital Aspergillus Infection

Aspergillus is a widespread, usually harmless saprophyte. Widespread infection in immune-compromised patients will usually present with endophthalmitis. In the orbit, infection with aspergillus may occur in immunocompetent<sup>14</sup> or immunocompromised patients<sup>15</sup> and usually invades from the adjacent sinuses but also may occur as an isolated orbital lesion with indolent onset.<sup>16</sup> Diagnosis requires identification of septate hyphae in tissue specimens. Treatment may require debridement (if possible) and long-term antifungals. Cavernous sinus and cranial involvement may be fatal.

#### Orbital Parasitical Infection

Parasitical orbital infections are rare in the West, but may be common in developing nations. The two principal types are cysticercosis and echinococcosis.

Cysticercosis is a parasitical infection caused by *Cysticercus cellulosae*, the larval form of the pork tapeworm *Taenia solium*. It occurs commonly in areas with poor hygiene. Cerebral cysticercosis is most common, but orbital involvement is not rare. It usually involves extraocular muscle.<sup>17</sup> Successful treatment with albendazole and prednisolone precludes surgery in almost all cases.<sup>17</sup>

Echinococcosis, or hydatid disease, is due to infection with the worm *Echinococcus granulosus*. The infection is widespread in certain parts of the world and primarily affects the liver. The orbit is rarely affected (0.3% of 3736 cases in one report from China).<sup>18</sup> Cysts develop gradually in the orbit in patients, usually with evidence of cysts elsewhere. The main treatment is surgical excision.

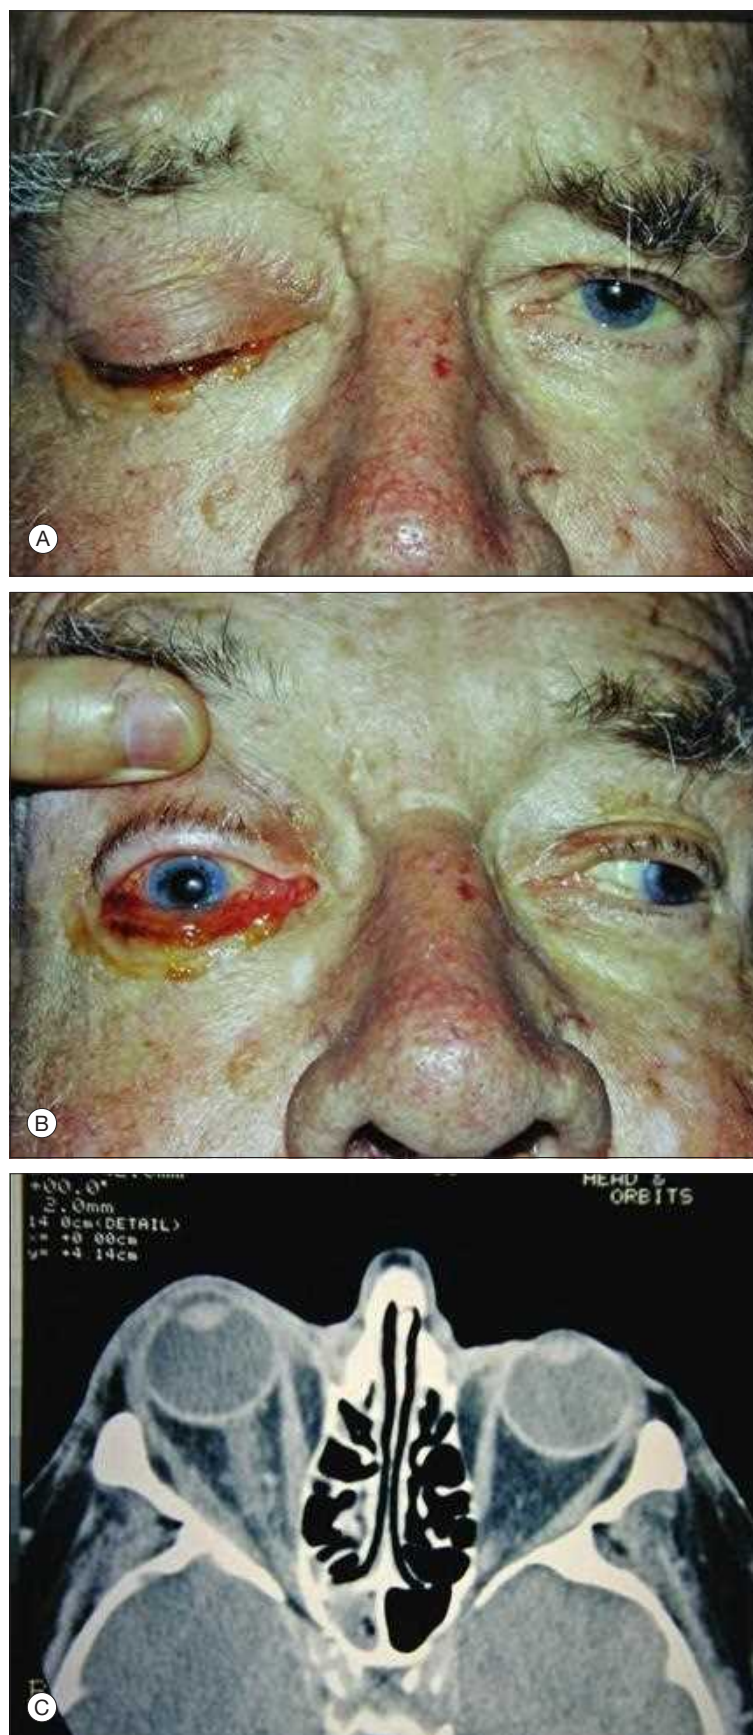

### Noninfectious Orbital Inflammation

Noninfectious orbital inflammation is common. The more common causes are listed in Table 12.14.3. By far the most common, Graves' orbitopathy, is discussed elsewhere (see Chapter 12.13). For many decades the term orbital pseudotumor was used to describe orbital inflammation where no cause could be identified, but the term has been largely supplanted by idiopathic (or nonspecific) orbital inflammation (IOI). This should be reserved for cases where no "specific" cause can be identified. Many "specific" forms of inflammation are just as "idiopathic" as IOI, but there are important pathological and clinical features of specific inflammatory disorders, including involvement of other organs.

Over time, the proportion of patients with orbital inflammation that can be labeled IOI has diminished. The largest recent cause of this reduction has been the recognition of IgG4-related disease.

#### Granulomatous Orbital Inflammation

Granulomatous inflammation is a specific form of inflammation characterized by the formation of granulomas with macrophages or histiocytes. Sarcoidosis is the most common cause of granulomatous inflammation in the orbit. Other causes of granulomatous inflammation such as

**Fig. 12.14.4** (A) and (B). An older man with diabetes presenting with 48 hours of rapidly progressive right proptosis, complete ptosis, and ophthalmoplegia and no perception of light and evidence of a central retinal artery occlusion due to mucormycosis. (C) An axial CT scan shows right proptosis, patchy change within the orbit, and relatively mild changes in the ethmoid and sphenoid sinuses.

**TABLE 12.14.3 Causes of Orbital Inflammation (Noninfectious)**

1. Specific
  - Graves' orbitopathy (not discussed in this chapter)
  - granulomatous
    - sarcoidosis
    - xanthogranulomatous
    - foreign body reaction
  - IgG4-related disease
  - vasculitic
    - granulomatosis with polyangiitis (Wegener's disease)
    - Churg–Strauss syndrome
    - others (giant cell arteritis, polyarteritis nodosa)
  - Sjögren's
  - others (Castleman's disease, Kimura's disease, Rosai–Dorfman disease)
2. Idiopathic orbital inflammation
  - by acuity or pathological process
    - acute
    - subacute
    - chronic
    - sclerosing
  - by anatomical site
    - orbital myositis
    - dacryoadenitis
    - anterior
    - diffuse
    - apical
3. Masquerade syndromes
  - rapid tumor growth (mimicking inflammation)
  - tumor necrosis (causing acute inflammation)

mycobacterial infection (tuberculosis), fungal infection, or foreign bodies must be excluded.

### Sarcoidosis

Uveitis due to sarcoidosis is far more common than orbital sarcoidosis, and strangely, the two are often not seen together. The most common orbital or ocular adnexal site of involvement is the lacrimal gland (42%–63%), which may be unilateral or bilateral,<sup>19–21</sup> (Fig. 12.14.5A–C) followed by the anterior orbit, usually inferiorly (13%–38%), the eyelid (11%–17%), and less commonly the lacrimal sac or optic nerve and sheath.

Angiotensin-converting enzyme levels are not commonly elevated in ocular adnexal sarcoidosis (20% in one series).<sup>20</sup> Concurrent systemic disease is common at presentation (50%),<sup>20</sup> with the diagnosis already known (37%)<sup>21</sup> or found on testing (a further 27%).<sup>21</sup> It may never be found (30%) or develop after some years.<sup>21</sup>

Treatment, if required, is usually with oral or local injection of corticosteroids or corticosteroid sparing agents such as methotrexate. Response rates are good.

### Xanthogranulomatous Disease

This group of diseases is rare and in adults comprises four entities: adult onset xanthogranuloma (AOX), adult onset asthma and periocular xanthogranuloma (AAPOX), necrobiotic xanthogranuloma (NBX), and Erdheim–Chester disease (ECD).<sup>22</sup> They are non-Langerhans' cell histiocytic disorders and have characteristic foamy macrophages and Touton giant cells present.

AOX, AAPOX, and NBX tend to involve the eyelids and anterior orbit, with swelling, erythema, and yellowish discoloration of tissues (Fig. 12.14.6A–C). AOX and AAPOX are usually bilateral and symmetrical. AOX and AAPOX respond well to rituximab.<sup>23</sup> NBX is often associated with hematological malignancies.

ECD usually involves both posterior orbits symmetrically and widely and is a systemic disease often affecting retroperitoneum, kidney, lung, long bones, pericardium, or meninges and is the only member of this group with an identified gene mutation (in the BRAF gene),<sup>24</sup> making it amenable to treatment with monoclonal antibodies.

### IgG4-Related Disease

IgG4-related disease (IgG4-RD) is a recently recognized entity characterized by tumefactive lesions with dense lymphoplasmacytic infiltration, rich in IgG4-positive plasma cells, fibrosis, usually of a storiform pattern, and in some organs, an obliterative phlebitis. Serum IgG4 levels may be elevated or normal. Large numbers of tissue eosinophils also may be seen.<sup>25</sup> It may affect one or more organs; the orbit and ocular adnexa are frequently involved (IgG4-related ophthalmic disease, IgG4-ROD). Almost any tissue

**Fig. 12.14.5** (A) A middle-aged man with several months of bilateral lacrimal gland enlargement due to sarcoidosis. On imaging, there is bilateral symmetrical enlargement of the lacrimal glands on both an axial CT scan (B) and an axial T1-weighted gadolinium-enhanced MRI (C).

may be affected, but the most common are pancreas, hepatobiliary tract, lymph nodes, and salivary glands.

The most commonly affected orbital tissues are lacrimal gland (Fig. 12.14.7A), orbital fat, extraocular muscle, and infraorbital nerve.<sup>26</sup> Enlargement of the infraorbital nerve by lymphoid hyperplasia is characteristic of this disorder (Fig. 12.14.7B).<sup>27</sup> Disease may be unilateral or bilateral. Bilateral disease is a strong indicator of likely systemic disease.<sup>28</sup>

Patients usually present with a subacute or chronic inflammatory process. Diagnosis requires biopsy and appropriate tissue immunohistochemistry.<sup>25</sup> The presence of IgG4+ plasma cells alone is insufficient for the diagnosis, and these may be seen in a variety of other conditions, especially xanthogranulomatous disease<sup>24</sup> and granulomatosis with polyangiitis.<sup>25</sup> A ratio of IgG4+ to IgG+ plasma cells over 40% may be more important than the actual number.

Treatment is usually with oral corticosteroids, but relapse is common on withdrawal. A variety of corticosteroid-sparing agents have been used, but rituximab is very effective.<sup>29</sup> An increased risk of the development of lymphoma exists with IgG4-RD.<sup>26</sup>

### Orbital Vasculitic Disease

The most common vasculitic disease to affect the orbit is granulomatosis with polyangiitis (GPA, formerly known as Wegener's granulomatosis). Churg–Strauss disease and polyarteritis nodosa rarely affect the orbit.

**Fig. 12.14.6** (A) An older man with unilateral left proptosis and eyelid swelling, lateral conjunctival chemosis, and yellowish discoloration of the eyelids due to adult onset xanthogranulomatous disease. This is usually bilateral. (B) A coronal CT scan from another patient with adult onset asthma and periocular xanthogranuloma (AAPOX) shows bilateral lacrimal gland infiltration with patchy extension into the adjacent soft tissues associated with paranasal sinus disease. (C) An axial CT of the patient in (A). (B) shows extension of the disease process along the lateral wall of the left orbit and extensive sinus disease.

Giant cell (or temporal) arteritis commonly affects the optic nerve but very rarely other orbital tissues.

### Granulomatosis With Polyangiitis

GPA is a granulomatous and sometimes necrotizing vasculitic disease that commonly affects the kidneys and lungs (generalized GPA). Untreated, it is fatal. Up to 60% of patients with generalized GPA will have orbital or adnexal disease.<sup>30</sup> Conversely, many patients present with a more localized form of the disease without systemic involvement.<sup>31,32</sup> In this group of

**Fig. 12.14.7** (A) An axial CT scan of a patient with IgG4-related ophthalmic disease (IgG4-ROD) manifesting as bilateral lacrimal gland enlargement. (B) A coronal CT scan of another patient with IgG4-ROD shows bilateral enlargement of several extraocular muscles, patchy infiltration along the left orbital roof, and enlargement of both infraorbital nerves (the left is larger and indicated by the arrow).

patients, the diagnosis may be difficult because of atypical biopsy findings and a negative c-ANCA.<sup>31,32</sup>

Patients present with orbital mass lesions, often adjacent to the sinuses (Fig. 12.14.8A,B), lacrimal gland disease, and sometimes ocular features such as scleritis, sclerokeratitis, or retinal vasculitis. The presence of nasal and paranasal sinus disease, usually with bone destruction (see Fig. 12.14.8B), is very suggestive of GPA.<sup>33,34</sup> A proportion of patients previously diagnosed with idiopathic orbital inflammation may have limited GPA on the basis of gene expression profiling of biopsies.<sup>35</sup>

Treatment is usually with corticosteroids and cyclophosphamide; more recently, rituximab has been shown to be very effective.

### Sjögren's Syndrome

Primary Sjögren's syndrome (pSS) is a common systemic autoimmune rheumatic disease causing sicca syndrome (dry mouth, nose, and eyes), swollen salivary glands (and sometimes lacrimal glands), and in some patients, joint, skin, lung, and other disease.<sup>36</sup> Depending on the duration of the disease, the lacrimal glands may be swollen,<sup>37</sup> normal in size, or atrophic. Diagnosis can be difficult and relies on serology (anti Ro and La autoantibodies) and labial salivary gland biopsies. Dry eye is usual but non-specific. Many cases previously diagnosed as "atypical Sjögren's syndrome" (negative serology) were probably IgG4-RD.

Sjögren's syndrome carries an increased risk of the development of non-Hodgkin's lymphoma,<sup>38</sup> and enlarged lacrimal glands in these patients should be biopsied to exclude lymphoma.

### Idiopathic Orbital Inflammation

IOI is a diagnosis of exclusion. More specific forms of inflammation (as described earlier) should be excluded, and tissue biopsy is the best way of doing this. However, where the presentation is sufficiently typical, or the risk of biopsy is high, a diagnosis of IOI may be made on the basis

**Fig. 12.14.8** (A) A 65-year-old man with several years of progressive diplopia, left epiphora, and a sunken appearance at the left medial canthus with a hard medial palpable mass. (B) A coronal CT scan shows a mass in the medial orbit involving the medial rectus muscle and the lacrimal drainage apparatus. There is loss of bone in the medial orbital wall and adjacent turbinates and ethmoid sinuses. He has a limited form of granulomatosis with polyangiitis, and is ANCA negative.

of clinical presentation and imaging without biopsy. Examples are typical orbital myositis and orbital apex IOI (Tolosa–Hunt syndrome).

Pain and periorbital swelling are the most common features.<sup>39</sup> The majority will respond to a slow tapering course of oral corticosteroids, but relapses or incomplete responses are common.<sup>39</sup> IOI may be acute, sub-acute, chronic, or sclerosing, the latter being a distinct clinicopathological entity,<sup>40,41</sup> although IgG4-ROD and GPA need to be excluded in this group. IOI can affect any orbital tissue, but there are several recognized anatomical patterns (see Table 12.14.3).

### Idiopathic Orbital Myositis

Idiopathic orbital myositis typically presents acutely with painful diplopia, a single extraocular muscle (EOM) involved, and rapid response to oral corticosteroids, usually in 1 mg/kg doses tapering over several weeks.<sup>42–44</sup> The involved muscle usually shows fusiform enlargement and involvement of the tendon. Other forms of inflammation of the EOMs should be excluded (IgG4-RD and other autoimmune conditions such as Crohn's disease), usually on the basis of a history of other disease and other organ or orbital tissue involvement.

Relapse after withdrawal of corticosteroids is common (56% in one series).<sup>42</sup> Repeat treatment with corticosteroids or corticosteroid-sparing agents may be required, but if the course is atypical, a biopsy should be obtained.

### Idiopathic Dacryoadenitis

Idiopathic dacryoadenitis is a diagnosis of exclusion and should be diagnosed only with a biopsy and appropriate investigations to exclude other conditions such as sarcoidosis, Sjögren's syndrome, IgG4-ROD, GPA, or lymphoma.

Idiopathic dacryoadenitis is more commonly unilateral, and inflammation may extend to adjacent fat and EOM. Incomplete response to treatment is associated with male gender and EOM involvement, and recurrence is more common in bilateral disease.<sup>45</sup>

### Tolosa–Hunt Syndrome (Orbital Apex IOI)

IOI of the orbital apex and superior orbital fissure is rare. It presents with pain, double vision, and sometimes sensory loss of the face and optic neuropathy.<sup>46</sup> Again, it is a diagnosis of exclusion.

## Cosmetic Blepharoplasty and Browplasty

12.15

François Codère, Nancy Tucker, Jonathan J. Dutton

**Definition:** Surgeries to correct changes in the eyelids and forehead area that are secondary to aging and manifest by redundancy and displacement of tissues.

## Key Features

- Facial aging results in bone remodeling with changes in soft tissue draping and midface fat atrophy.
- Any aesthetic eyelid or brow surgery must evaluate the patient's complaints and goals.
- Detailed examination is mandatory to uncover specific anatomical abnormalities that need to be addressed.
- When brow and eyelid surgery are planned, the brow should be elevated first to avoid removing too much upper eyelid skin.

## INTRODUCTION

Aging changes in the face involve progressive remodeling of the facial skeleton with bone projection in the forehead and brows and facial regression in the mid and lower face. Loss of collagen and elastin in the various layers of the skin and subcutaneous tissues is seen in the eyelids and midface. Changes that occur in the upper eyelid skin are compounded due to passive stretching, loss of support, or redundancy of skin secondary to lowering of the brows.

Most patients do not appreciate the extent to which brow malposition contributes to the overall appearance of the aging periorbital area. This needs to be pointed out specifically to help them understand why a blepharoplasty alone often will not fully correct the problem. If a manual lift of the brow to the desired position significantly improves the patient's appearance, a browplasty—either alone or combined with blepharoplasty—should be considered. If a blepharoplasty is performed without recognizing any associated brow ptosis, the lateral eyebrow can appear pulled down, which produces an undesirable sad appearance.

## ANATOMICAL CONSIDERATIONS

## Eyelids

Key anatomical features that cause excess upper eyelid skin include brow ptosis from the loss of forehead deep tissue support, loss of the deep invagination of the eyelid skin in the principal lid crease as a result of anterior displacement of the suborbicularis fat pads, and stretching of attachments between the levator aponeurosis and the skin. For the sake of understanding the anatomy, the lid may be divided arbitrarily into two distinct portions (Fig. 12.15.1).

## Upper Eyelid

Anatomy of the upper eyelid is discussed in Chapter 12.1. The eyelid crease is an important anatomical and aesthetic landmark. The skin and muscle between the crease and the brow form the eyelid skin fold. If upper lid fat recedes or the levator aponeurosis becomes stretched or disinserted, the crease assumes a higher position. In the Asian eyelid, the crease (if present) is lower because of the low insertion of the orbital septum into the aponeurosis with consequent descent of the preaponeurotic fat pockets.<sup>1</sup>

When the eyelid opens, the lid crease skin is pulled upward and backward by the aponeurosis as it retracts under the fat pad (Fig. 12.15.2).<sup>2</sup> The

eyelid fold then bulges slightly as this fat pushes the skin forward. During downgaze, tension in the aponeurosis becomes lax, resulting in a weakened or absent lid crease.

## Lower Eyelid

The lower eyelid has a similar but simpler anatomy and is reviewed in Chapter 12.1. Integrity of the medial and lateral canthal tendons is very important to maintain a proper lid position, especially in the aging face.<sup>3</sup> However, the bony configuration of the midface also plays a key role. Because the lower eyelid is less mobile than the upper, less redundancy

**Fig. 12.15.1 The Orbital Septum Inserts Into the Levator Aponeurosis (Arrows).** The preaponeurotic fat pads are located posterior to the septum. In downgaze the lid crease becomes attenuated (weakened), and in a normal young eyelid the fold is absent. (Adapted with permission from Zide BW, Jelks BW. Surgical anatomy of the orbit. New York: Raven Press; 1985 [chapter 4]. p. 23.)

**Fig. 12.15.2** The Invagination of the Normal Eyelid Crease Is Created by the Posterior Pull on the Septal Insertion by the Elevating Levator Aponeurosis. The preaponeurotic fat is also retracted by the septum. The flat portion of the lid under the crease slips inside the upper preseptal portion. (Adapted with permission from Zide BW, Jellus BW. *Surgical anatomy of the orbit*. New York: Raven Press; 1985 [chapter 4]. p. 23.)

of the skin and muscle occurs. The major aging changes include sagging of skin, deepening of wrinkles, descent of the lateral canthus from loss of bony support, and atrophy of subcutaneous fat.

## Brows

A thorough understanding of the forehead anatomy is essential to evaluate brow ptosis (Fig. 12.15.3).<sup>4</sup> The layers in the midforehead are skin, dermis, superficial galea, frontalis muscle, deep galea, and periosteum. The forehead skin is much thicker than the eyelid skin. The dermis and subcutaneous fat are connected to the underlying frontalis muscle by multiple fibrous septa. The paired frontalis muscles originate just anterior to the coronal suture line. A smooth fibrous sheath, the galea aponeurotica, envelops the frontalis to form both superficial and deep galeal layers.

Laterally, the frontalis muscle ends and does not extend beneath the lateral third of the brow. Here the superficial galea, the superficial temporal fascia, and the periosteum of the frontal bone fuse. The confluence of these tissue planes is called the “zone of fixation.” The eyebrow fat pad (subgaleal fat pad) is a transverse band of fibroadipose tissue 2–2.5 cm above the orbital rim. It allows movement of the frontalis muscle in the lower forehead.

Medially, the procerus muscle is continuous with the medial portion of the frontalis muscle and inserts into the nasal bone and glabellar subcutaneous tissue. It causes horizontal wrinkles of the glabella.<sup>5</sup> The corrugator supercilii muscle is obliquely oriented, passing from the subcutaneous brow to the frontal bone medially. It causes vertical glabellar furrows.<sup>6,7</sup>

Several important neurovascular structures occur in the forehead. The frontal branch of the facial nerve lies within the superficial temporal fascia before entering the deep surface of the frontalis muscle. Several nerves are found along the superior orbital rim: the lacrimal nerve laterally, the supraorbital nerve with its deep and superficial divisions centrally, and the supratrochlear nerve more nasally.

Several factors contribute to the appearance of the aging forehead and brow. These include changes in the quality of the skin, loss of tissue support, and horizontal forehead and glabellar furrows related to action

**Fig. 12.15.3** Surgical Anatomy of the Forehead Muscles and Fascia.

of the underlying facial muscles.<sup>8,9</sup> The lateral eyebrow segment is more prone to becoming ptotic because of less structural support in this area. The final brow position depends on the dynamics between the frontalis muscle pulling the brow up and the descending temporal soft tissue and lateral orbicularis muscle dragging it down.<sup>7</sup>

## BLEPHAROPLASTY

### Preoperative Evaluation and Diagnostic Approach

#### History and Psychological Evaluation

When evaluating patients who seek cosmetic improvement of the periorbital area, the surgeon should understand the patients' motives for undergoing surgery and the decision-making process they have undertaken. Asking patients what they expect the surgery will change for them can sometimes reveal unexpected motives or unrealistic expectations. The psychological screening should include a medical and surgical history with specific questions about previous cosmetic surgery. Outcomes of previous surgeries might give a clue to unrealistic expectations, especially if the objective results of these previous surgeries are not in harmony with the patient's perception. Previous mental illness should alert the surgeon—a psychiatric consultation is sometimes useful.

In assessing expectations, the surgeon can help by carefully discussing the surgery and explaining the improvements to be expected. It is important to detail the cosmetic defects that cannot be changed by surgery and establish a realistic plan for facial rejuvenation.<sup>10</sup>

The patient is asked to consider carefully the decision to undergo surgery and, if one is sought, should be encouraged to obtain a second opinion. Establishing a relationship of trust is of paramount importance. If in any doubt, even for unclear objective reasons, a conservative attitude is recommended.

#### Physical Examination

The position and shape of the different periorbital structures are evaluated along with the quality of the skin.<sup>5,11</sup> In the forehead area, the level and shape of the hairline, the quality of skin of the forehead, and the position and shape of the brows are evaluated with specific attention to detecting brow asymmetry. The muscular layer is judged by looking at the frown lines in the forehead and glabellar area and by asking the patient to relax the forehead. The bony orbit is then evaluated, especially laterally at the orbital rim, where some prominence can mimic lacrimal gland prolapse. This is a good time to evaluate the position of the globe in relation to the

## WORKSHEET TO DOCUMENT PHYSICAL FINDINGS AND SURGICAL PLAN

**Physical Findings:**

- Brow ptosis:
- Corrugator?: ☐
- Procerus?: ☐
- Exophthalmos?: ☐
- Lid retraction?: ☐
- Type lift -
- Skin resection:
- Upper- (right)
- Aperture deformities?: ☐
- Tone:

**Fig. 12.15.4 A Sample Worksheet to Document the Physical Findings and Surgical Plan.** (Adapted with permission from Flowers RS, Flowers SS. Precision planning in blepharoplasty. Clin Plast Surg 1993;20:303-10.)

bony orbit, as this is an important determinant of the type of lid fold to aim for. A fuller orbit with a large eye leads to a convex upper eyelid above the crease, whereas a large orbit with a small eye results in a more concave upper lid above the crease. A prominent globe with recessed zygoma often leads to lower lid malposition.

For the eyelids, precise measurements of the eyelid vertical and horizontal apertures should be recorded, noting the high point of the upper lid both from the lower lid and from the mid pupil. The general shape of the palpebral fissure is noted. The position of the lid crease and upper eyelid skin fold should be documented. The amount of fat to be removed in all fat pad areas is estimated, and any prolapse of the lacrimal glands is noted. In the lower lids the fat pads are carefully assessed, with any areas of prolapse noted. The inferior periorbital area over the upper cheek is evaluated in a similar fashion. The quality of the skin is important, and cicatricial changes from dermatological conditions or chronic sun exposure can make the lid more susceptible to malposition after surgery. The cheek is examined for the presence of festoons, noting whether they consist of only skin and orbicularis muscle or also of suborbicularis fascia and/or orbital fat.<sup>12</sup> The lower lid is assessed with the distraction test by pulling the central lower lid margin away from the eye. A distance of more than 6 mm is considered abnormal and may require a lift tightening. The position of the lateral canthus is noted and normally is 1-2 mm higher than the medial canthus. As an aging phenomenon, the lateral canthus is often lower. Laxity of the canthal tendons is noted and if present is manually tightened with the finger before estimating the amount of skin to be removed. The nasojugal area should be examined to detect tear trough deformities, which may need correction instead of fat pad removal.<sup>13</sup>

The use of a flow sheet to outline systematically the physical findings is an excellent way to plan present and future surgery. Surgical planning must take into account the patient's desires, what he or she is willing to undergo, and what the surgeon thinks is reasonable and safe. Fig. 12.15.4 gives an overview of the patient consultation evaluation for blepharoplasty and correction of any brow malposition. A good set of photographs should carefully document the changes noted and must be kept as part of the patient's medical record.

## Anesthesia

Local infiltrative anesthesia containing epinephrine for hemostasis is adequate for all blepharoplasty procedures. Some surgeons prefer a supraorbital and supratrochlear nerve block.

## General Techniques

Draping should be done carefully to avoid distortion of the brow and lateral canthi and to allow the patient to sit up, if necessary, during the operation. The amount of skin to be removed is marked before infiltration of anesthetic, which will distort the tissues. In the upper eyelid, excessive removal of thin lid skin may result in a dragging down of thick brow skin and should not be substituted for first repositioning the brows. In the lower lids the same principle applies: The lid should be repositioned and the scleral show corrected with appropriate lateral canthal surgery before any skin is removed.

## Specific Techniques

### Upper Lid Blepharoplasty

Before upper eyelid blepharoplasty is begun, the brow should be repositioned as needed, especially lateral brow droop. A proposed skin incision is marked in the existing eyelid crease, or if there is no visible crease, the line is marked about 8-10 mm above the lash line, taking into account the racial background of the patient. The crease marking usually goes from a point above the superior punctum to—but not beyond—the lateral orbital rim. Skin excess is evaluated by placing one arm of a forceps on the crease incision line and pinching the redundant skin within the opposite arm so that in downgaze the skin is tight without lagophthalmos. In general, 20-24 mm of skin should be left between the brow and the lid margin to prevent postoperative lagophthalmos.<sup>14</sup> The long-taught rule that the eyes should not close on the operating table has certainly become obsolete. Excessive skin removal medially may result in hood formation. If disproportionate tissue is still present in this region after surgery, a glabellar lift can be considered. An optional small triangular flap of skin can be added to the usual skin pattern medially to minimize folding of the skin at the time of closure in patients with excess of skin medially (Fig. 12.15.5).

The lid is placed under downward traction, and a Bard-Parker No. 15 blade is used to incise the skin. The skin flap is removed with a blade or scissors, leaving the orbicularis muscle intact at this stage.

Gentle pressure on the globe will prolapse the orbital fat pockets that bulge behind the orbicularis muscle and orbital septum. The fat is exposed by a small buttonhole that is made centrally through the orbicularis and the septum above its insertion on the aponeurosis. The septum is opened laterally and medially from this buttonhole (Fig. 12.15.6). Each fat pad

capsule is opened. The fat is gently prolapsed and transected. The section line is cauterized with a bipolar cautery (see Fig. 12.15.6).

The orbicularis muscle is thinned, but some surgeons prefer to remove it completely along with the overlying skin. The aponeurosis is exposed above the tarsal border. Invagination of the skin by fixing the skin edge to the aponeurosis at the time of closure ensures a good position of the crease in fuller lids but is not always necessary. The orbicularis can be tacked down to the aponeurosis immediately under the upper skin edge using two or three 6-0 plain sutures. This defines the position of the eyelid crease and controls the position of the fat pad in the lid (Fig. 12.15.7). The skin is closed with a running 6-0 nylon or 6-0 plain gut suture. The area beyond the lateral canthal angle is closed with interrupted sutures to obtain an edge-to-edge closure without folds (Fig. 12.15.8).

### Lower Lid Blepharoplasty

Two specific techniques are popular for lower lid blepharoplasty.<sup>15</sup> The skin approach allows modification of the interaction between the muscle and the skin planes and makes lid tightening or canthal repositioning easier. When only fat prolapse is present, the transconjunctival approach allows surgical access without a visible scar and avoids the risk of lid malposition.

### Skin Approach

In the skin approach, the skin is marked 3 mm below the lash line from the inferior punctum to the lateral canthal angle. If excess skin is to be

removed or if the orbicularis muscle is to be tightened, the incision is extended laterally and downward toward the earlobe for a short distance.

The skin and orbicularis muscle are incised with a No. 15 blade. Scissor dissection exposes the suborbicularis plane and the anterior surface of the orbital septum. The septum is easily identified with a gentle push on the globe to prolapse the fat and is opened with scissors. The temporal and central fat pads are one continuous pad separated by a vertical band of fascial connections between the capsulopalpebral fascia and the orbital septum.<sup>3</sup> The capsule of each fat pad is opened. Care is taken to tease the fat out of the respective pockets without undue traction in order to avoid deep bleeding in the orbit. In the medial lid the fat capsule is opened separately; care must be taken to protect the inferior oblique muscle, which lies between the medial and central fat pockets. The fat is carefully examined for bleeders before it is allowed to retract into the orbit. In some cases, repositioning of the lower eyelid orbital fat into the suborbicularis oculi fat (SOOF) plane is another useful procedure to fill in a tear trough deformity.<sup>16</sup>

A canthopexy can be used to lift a sagging lateral canthal angle through placement of a suture through the lateral canthal tendon that is attached to periosteum.<sup>17</sup> If horizontal lid laxity is present, a tarsal strip procedure can be performed (see Chapter 12.6).<sup>18</sup> A small triangle of skin and orbicularis muscle may be excised laterally to prevent a dog-ear. Closure of the orbicularis as a sliding flap often helps to rejuvenate an older lid. Hemostasis is attained carefully before the skin is closed with a continuous suture of 6-0 nylon or 6-0 plain gut.

### Transconjunctival Approach

With the transconjunctival approach, the lid is everted over a Desmarres retractor. The retractor is used to pull the lid toward the cheek to expose the conjunctiva and fat pads. The lateral fat pad is often the most difficult to expose—a buttonhole through the conjunctiva laterally about 4 mm from the inferior tarsal border can be helpful. The fat is prolapsed through the defect, cauterized at the base, and carefully cut with fine scissors. This approach allows early identification of the lateral fat pad before any bleeding occurs. The conjunctival incision then can be extended medially to expose the central and medial pads, which are removed in the same way. Closure of the conjunctiva is completed with a few 6-0 plain catgut sutures.

### Other Surgical Techniques

Specific techniques should be used when operating on Asian eyelids—the goals determine the technique to be used.<sup>19</sup> In general, the skin incision is made lower toward the lid margin, depending on the desired position of the resulting crease.<sup>20</sup> Some preaponeurotic fat should be left to act as a barrier between the levator and the skin if the Asian-type lid is to be preserved. Other minimally invasive adjuncts can be added to upper lid

**Fig. 12.15.5 Typical Skin Incision Line Used for Upper Eyelid Blepharoplasty.** A small additional medial flap is added (shaded area) if a dog-ear or fold develops because of excessive skin nasally.

**Fig. 12.15.6 Exposure and Cauterization of Fat Pads.** Preaponeurotic fat pads are a key landmark just anterior to the aponeurosis. The orbital septum is opened to expose the fat, and each pad is carefully cauterized along its base before being cut with scissors.

**Fig. 12.15.7** The Eyelid Fold or Crease Is Reformed by Passing Several Sutures From the Orbicularis Muscle to the Aponeurosis at the Appropriate Height.

**Fig. 12.15.8** The Skin Is Closed With Two to Three Interrupted Sutures Laterally, Where the Skin Is Thicker, and With a Running Suture Along the Remainder of the Wound.

blepharoplasty to enhance the surgical results and patient satisfaction. These include internal browpexy, fat redistribution, and lacrimal gland repositioning.<sup>21</sup>

## Postoperative Care

A medium-pressure bandage is applied to the lids with an appropriate antibiotic ointment. The patient can remove the patches soon after surgery and start applying cold packs to the surgical site for 20 minutes each hour during the first evening and then four or five times the next day. Light analgesia for blepharoplasty is usually sufficient. Severe pain is not expected and warrants immediate examination to rule out orbital hemorrhage, infection, or corneal abrasion. The sutures on the skin can be removed 5–7 days postoperatively if 6–0 nylon is used.

## Complications

Blepharoplasty is one of most common operations performed and the least invasive cosmetic procedure. Nevertheless, devastating complications can occur, including blindness. Most complications result from unrecognized anatomical abnormalities or from errors in measurement or excessive removal of tissue.<sup>22</sup>

Complications of blepharoplasty are of two orders. One group of complications can occur from events unrelated to the technique used; a second group can occur following improper surgery for particular deformities. For

example, despite the best surgical technique, infection will occur in a small number of patients; the same is true of milia formation along a scar line. Lower lid ectropion or canthal angle rounding in the lower eyelid is usually the result of improper surgical planning or techniques.

## Orbital Hemorrhage and Blindness

Orbital hemorrhage following blepharoplasty is an emergency. It has been associated with permanent loss of vision in some cases, especially if the lower eyelid is involved.<sup>14,23,24</sup> Prevention involves careful preoperative screening for the use of anticoagulants, including aspirin. Meticulous hemostasis, gentle manipulation of fat during surgery, and good control of blood pressure postoperatively are important. Early removal of patches and application of cold packs will minimize swelling. Strenuous activities should be avoided for the first 3–4 days. Anticoagulants should not be restarted for at least 5–6 days after surgery. The surgeon and medical staff should be alerted by unusual pain, swelling under tension, or double or blurred vision. If in doubt, the patient must be seen immediately for an assessment of visual acuity and pupillary response. In the presence of a deep hematoma the patient should be admitted for close monitoring of optic nerve function. If optic nerve dysfunction appears, the wounds are opened and the blood is evacuated. A lateral cantholysis helps decompress the soft tissues of the orbit, but with a deep hemorrhage, an orbital exploration may be required.

## Infections

Fortunately, the eyelids are well vascularized so that infections after blepharoplasty are rare. Patients should be aware that an increase in swelling with redness and pain might be the first sign of infection. If it is confirmed by examination, appropriate cultures and sensitivities should be obtained and the patient started immediately on wide-spectrum systemic antibiotics. Close follow-up to rule out abscess formation in the orbit is necessary in severe cases, and proper orbital imaging should be obtained. Blindness is a rare complication of infection, but it has occurred following blepharoplasty.<sup>25</sup>

## Ptosis

Ptosis may be present but unrecognized on initial preoperative examination in patients with severe skin excess. Palpebral fissures should be evaluated along with the levator action as if all patients were consulting for ptosis (see Chapter 12.4). If present, ptosis should be corrected by advancing the levator aponeurosis on the tarsal surface. Otherwise, at the time of blepharoplasty, care should be taken not to damage the aponeurosis. If impending ptosis is present and the lid crease is reconstructed by supratarsal fixation, a slight tightening of the aponeurosis may be wise. When ptosis appears after surgery, conservative observation for 6 months is recommended. If it persists, surgical correction may be necessary.

## Lagophthalmos, Lower Lid Retraction, Ectropion, and Lateral Canthal Deformities

If excessive skin has been removed in the upper lid, resulting in lagophthalmos, time is often of help; the brows continue their downward drift and the lagophthalmos often progressively decreases. Massage and ocular lubricants in the first few months after surgery may bring the patient out of this difficult phase. But if keratitis ensues and threatens the integrity of the eye, surgical correction should be done. In the lower lid, gravity works against spontaneous improvement. Frank ectropion might resolve with massage but almost invariably leaves lower scleral show. Using the transconjunctival approach when minimal or no skin excess is present, tightening the lateral canthal tendon if necessary, and avoiding excessive skin removal are the best ways to prevent this complication.<sup>26</sup> Revision using a lateral tarsal strip procedure combined with a disinsertion of the lower eyelid retractors can give satisfactory results in mild cases. A midfacial lift or a skin graft may become necessary with more severe deformities.<sup>27–31</sup>

## Other Complications

Tearing after blepharoplasty can be a complex problem, especially if lagophthalmos is present. Investigation of this complication should include a full lacrimal workup with assessment of the reflex component if keratitis is present. The integrity of the canaliculi and the position of the lid margin and puncta are all evaluated before correction is planned (see Chapter 12.13). Injury to the extraocular muscles can occur, especially in the lower lid where the inferior oblique and inferior rectus are prone to damage with

exploration of the medial fat pad.<sup>32</sup> The superior oblique tendon can also be damaged in upper lid surgery.<sup>33</sup> In these instances, a follow-up of at least 6 months is necessary before surgical interventions are considered, as spontaneous resolution is fortunately the rule.

## Outcome

Most patients who seek cosmetic eyelid or brow surgery expect some improvement in their appearance and in their self-image and are usually happy with the result. Some, in whom the anatomical deformity interferes with visual function (as in severe overhanging dermatochalasis), can also notice improvement in their visual field. Patients who enter into surgery with unrealistic goals, either physical or social, are more at risk of not being satisfied with the results.

## BROW MALPOSITION

### Preoperative Evaluation and Diagnostic Approach

The ideal brow position and shape are subjective, but in general the brow is straighter and at the superior orbital rim in a man and more curved and slightly above the rim in a woman. An evaluation of the most cosmetically pleasing brows in women suggests that the medial eyebrow should be positioned at or below the supraorbital rim, with the eyebrow shape having an apex lateral slant.<sup>34</sup>

The clinical evaluation should include brow position (estimated by the difference between the actual resting brow position and the desired position), the amount of excess forehead skin and degree of furrowing, the hairline position, and the length of the forehead. The length of the forehead can be determined by passing imaginary horizontal lines through the hairline, the upper border of the eyebrows, and directly below the nose. These lines divide the balanced face into three equal portions. An increase or reduction of the upper segment is an important factor when selecting the incision site using the coronal approach.<sup>35</sup> The extent to which the procerus and corrugator muscles contribute to furrowing of the forehead should be determined. A family history of male pattern baldness should be sought. It is important to determine how extensive a surgery the patient is willing to undergo to achieve the best results. Often the final surgical choice is a compromise between the most effective technique and the least invasive procedure.<sup>36</sup>

## Anesthesia

Anesthesia is provided by supraorbital and supratrochlear regional blocks along with direct local infiltration, depending on the extent of anesthesia desired for each of the various techniques. In selected patients, general anesthesia may be considered. Gentle but constant pressure minimizes the formation of hematomas that can distort anatomy.

## General Techniques

Surgical approaches to the correction of brow ptosis include the direct, midfrontal, and endoscopic brow lift; transblepharoplasty fixation; and the bicoronal brow lift (Fig. 12.15.9). The choice of technique depends on the amount of correction required and on the patient's expectations.<sup>37</sup>

## Specific Techniques

### The Bicoronal Forehead Lift

The bicoronal forehead lift allows the maximal effect of brow elevation with a well-camouflaged incision site.<sup>38</sup> It is ideally suited for patients with significant brow ptosis, without frontal baldness, and with a normal to low hairline.

The incision is hidden posterior to the hairline (posttrichion). Alternatively, in patients who have a high forehead, the incision can be placed at the hairline (pretrichion) to avoid further elevating the hairline. There are two major choices for the surgical dissection plane: subcutaneous and subgaleal.<sup>35</sup> Factors that influence the choice of dissection plane include the quality and elasticity of the skin, the amount of skin wrinkling, and the depth of the furrows, but surgeon preference is likely to be the most significant factor.<sup>8,35</sup> A combined coronal brow lift and blepharoplasty can be used in patients with excessive eyelid fat and brow ptosis but little or no dermatochalasis.<sup>39</sup> The major disadvantages of the bicoronal technique include its invasive surgical approach, which can be intimidating to the patient, and the increased risk of hematoma and nerve injury.

Fig. 12.15.9 Surgical Incision Sites for Correction of Brow Ptosis.

### The Midfrontal Brow Lift

The midfrontal approach provides less brow lift effect than does the bicoronal but more than the direct brow lift approach. Advantages include less risk of hematoma (because only moderate undermining is required and it is performed above the frontalis muscle) and less risk of nerve damage. The corrugator supercilii and procerus may be resected directly through this approach. It is ideally suited for patients who have deep horizontal furrows in the forehead (usually men), especially when frontal baldness prevents the use of a bicoronal incision. There are various types of incisions that can be used:

- Along a furrow line the entire length of the forehead.
- Along a furrow line staggered centrally.
- Two separate fusiform excisions, each extending from the medial to lateral end of the brow.

The major disadvantage of this technique is the resultant scar line.

### The Direct Brow Lift

The direct brow lift is the oldest and simplest surgical approach. Its advantages include a less invasive surgical dissection with less risk of damage to the facial nerve and minimal risk of hematoma. It is ideally suited for patients with bushy brows and mild brow ptosis. It also can be used in patients who have unilateral brow ptosis, which most commonly occurs following peripheral facial nerve palsy. It does not fully correct the medial brow ptosis, and it results in a visible scar even when placed directly above the eyebrow with often an unnaturally sharp border due to loss of the fine upper brow hairs. In patients who have large bushy brows, the incision tends to be less apparent. Modifications include a more temporal skin excision to correct isolated temporal brow ptosis.

### Endoscopic Brow Lift

Recently less invasive techniques have emerged in an attempt to reduce complications and achieve faster recovery. These techniques include endoscopic procedures, which involve small incisions placed temporally and/or centrally on the scalp posterior to the hairline.<sup>40</sup> A subperiosteal or subgaleal dissection is carried down to the level of the brow. The procerus and corrugator muscles are usually cut and excised, and the periosteum is transected at the superior orbital rim. The forehead is pulled upward and the periosteum fixed into position.

### **Transblepharoplasty Brow Fixation**

For minimal brow ptosis, especially laterally, the brow can be elevated through a blepharoplasty incision through suturing of the subbrow dermis higher on to the frontalis muscle or periosteum. This approach can help correct mild brow ptosis or small asymmetries.<sup>36,41</sup> An absorbable Endotine fixation device has been advocated to fix the deep frontalis galea to the brow rim periosteum with significant brow elevation.<sup>42,43</sup>

### **Complications**

Complications of browplasty depend on the technique used. There are two major groups of complications: those related to the incision site and those related to the extent of dissection.

#### ***Excessive Cutaneous Scar and Alopecia***

The forehead skin is thicker and less vascular than the eyelid skin, so incisions in the forehead often heal with a visible scar. Meticulous closure with adequate subdermal tension-bearing sutures and careful approximation of the wound edges is important. However, placement of the incision is the main determinant of scar visibility. It is generally preferable to locate the incision site at or above the hairline. Alopecia can be secondary to tension of wound, ischemia, or superficial dissection.

#### ***Paresthesia and Hematoma***

Related to the extent of dissection are the potential associated nerve injuries, which can result in frontal paresis, numbness, and an increased risk of hematoma formation. Temporary paresthesia following browplasty is common but usually resolves within 6 months. Hematomas can occur after bicoronal brow lift. They can be prevented at the end of surgery by placement of suction drains under the flaps. Small hematomas often resolve spontaneously, but larger ones should be evacuated to avoid flap necrosis, especially with a subcutaneous dissection where necrosis is more likely.

#### ***Overcorrection and Undercorrection***

Overcorrection of brow position or loss of movement of the brow can result in a “look of perpetual surprise,” particularly if the brow has been

fixed to the underlying periosteum in an overzealous direct brow lift. Undercorrection occurs when insufficient elevation is achieved; it is more common with the endoscopic technique and with posterior fixation of the brow through a blepharoplasty incision.

### **Outcome**

Following brow elevation procedures, the patient should experience an improvement in appearance and a restoration of superior visual field. In order to achieve these results, the brow repair may have to be combined with a blepharoplasty.

# Aesthetic Fillers and Botulinum Toxin for Wrinkle Reduction

12.16

Jean Carruthers, Alastair Carruthers

**Definition:** The use of neuromodulators to adjust the power of muscles of facial expression has become the most popular aesthetic treatment worldwide. Changing the contours of the aging face with the use of three-dimensional fillers is a powerful adjunctive treatment.

## Key Features

- The functional and aesthetic importance of the periorbital region.
- Mechanisms of action of neuromodulators.
- Soft tissue augmentation mechanisms.
- As in surgery, a knowledge of anatomy of the facial regions is crucial both for superior results and for patient safety.

## INTRODUCTION

A focal point of attraction,<sup>1</sup> the periorbital region is one of the first areas of the face to manifest early signs of aging.<sup>2</sup> In youth, the forehead is high and gently rounded, the brow well defined and of appropriate height and shape, the upper orbit full, with a crisp upper eyelid crease and a lower lid that transitions smoothly to the cheek. Over time, these smooth contours are lost. Bony changes and atrophy of subcutaneous soft tissues lead to a loss of cutaneous support. It is this loss of skeletal and soft-tissue support that has the greatest impact on the appearance of the aging face.<sup>2-5</sup> As the skin repositions itself over the changing landscape of the face, the brow sinks toward the orbital rim, wrinkles bloom between and around the eyes, and the eye itself takes on a hollow, skeletonized appearance.

The multifactorial nature of aging provides the rationale for a combined, panfacial approach that simultaneously targets loss of support and volume and the appearance of wrinkles as indicated.<sup>6,7</sup> Rejuvenation of the periorbital region using soft-tissue fillers and botulinum neurotoxin type A (BoNTA) restores harmony and balance that has been lost during the aging process. However, the highly innervated and vascularized upper face requires a cautious approach and a deft touch. A thorough knowledge of anatomy and the interaction between musculature and the surrounding soft tissue is the key to consistent, favorable outcomes.

## APPROACH TO PERIORBITAL REJUVENATION

The periorbital region is prone to early manifestations of aging. The brow lowers progressively because of loss of structural forehead support (bone and fat), a decrease in neocollagenesis in the skin and facial planes, and the repetitive activity of the depressor muscles pulling on the inelastic skin of the forehead.<sup>8</sup> Mimetic musculature leads to the formation of glabellar rhytides and horizontal lines in the forehead that become more pronounced over time and produces lateral canthal and infraorbital rhytides, while the forehead and temples lose soft-tissue fullness.<sup>9</sup> Bony resorption widens the orbital cavity, giving the eye a sunken or shadowed appearance. The upper eyelid—the thinnest skin on the body with little to no subcutaneous fat—is prone to further thinning and stretching, whereas the lower lid is subject to fat redistribution, laxity, and weakening of the connective tissue.

The recognition of volume loss as a cardinal feature of aging has had a significant and lasting impact on the approach to facial rejuvenation with

injectable agents. The original treatment paradigm—using fillers or BoNTA separately in clearly delineated areas—has shifted toward more equal use of toxin and fillers in all facial zones with the objective of restoring youthful contours and creating facial proportions that more closely approximate the ideals of beauty. When used in combination throughout the face, neuromodulators and fillers work in synergy to produce optimal and durable aesthetic outcomes. It is an ideal marriage: Fillers correct volume loss in the periorbital complex and fill deeper folds and static wrinkles that cannot be alleviated by BoNTA alone.<sup>7</sup>

## Botulinum Toxin

Derived from the bacterium *Clostridium botulinum*, BoNTA blocks the release of acetylcholine from motor neurons at the neuromuscular junction, producing temporary chemodenervation of muscles lasting upward of 3 months.<sup>10</sup> Of the seven serotypes, type A is the most widely used across the world in multiple formulations for cosmetic and therapeutic indications. BoNTA has a long history of use in the periorcular region and was first used as an alternative to surgery in patients with strabismus.<sup>11</sup> Since its introduction for the treatment of glabellar rhytides over two decades ago,<sup>12</sup> BoNTA has become the most frequently performed cosmetic procedure in the world and is considered the gold standard treatment for dynamic facial wrinkles.<sup>13</sup> Moreover, progressive reduction in wrinkle severity and improvements in skin quality and biomechanical properties have been observed after repeated treatments over a long period of time,<sup>14-18</sup> suggesting that the effects of BoNTA go beyond muscle paralysis.

Of the available formulations, onabotulinumtoxinA (Botox Cosmetic, Allergan Inc., Irvine, CA) has the most approved clinical indications and has been the most widely studied for cosmetic and therapeutic purposes.<sup>6</sup> Subsequently, all doses discussed herein refer to onabotulinumtoxinA.

## Fillers

Although there is a wide variety of fillers on the market today, hyaluronic acid (HA) is most suitable for the delicate skin of the periorbital area. HA occurs naturally in the skin, making up a significant portion of the extracellular matrix involved in tissue repair, structural support, and cell proliferation and migration.<sup>19</sup> Injectable cross-linked HA derivatives, cultivated from the synthetic fermentation of the *Streptococcus equus* bacterium, attract and bind to water in the skin for immediate volume enhancement and appear to induce neocollagenesis via mechanical stretching for more persistent aesthetic effects.<sup>20</sup> HA fillers are available in multiple formulations. Highly viscous fillers provide greater lift and are ideal for deeper implantation, whereas products with low viscoelasticity are lighter and better suited for more superficial injection.<sup>21</sup> Importantly, HA is the only filler on the market that is considered “reversible,” in that unwanted or misplaced HA may be dissolved with the injection of hyaluronidase.<sup>22,23</sup>

## ANATOMICAL CONSIDERATIONS

The upper face is an area of substantial physical variability and anatomically unforgiving with respect to safety and aesthetic considerations. A thorough knowledge of periorbital musculature, vasculature (Fig. 12.16.1), and innervation is critical in achieving optimal outcomes and avoiding potentially catastrophic adverse events (see “Precautions” section).

Four muscles—the corrugator supercilii, procerus, depressor supercilii, and orbicularis oris—work together to cause the head of the brow to rotate medially and descend in the frown.<sup>24</sup> The frontalis, the sole elevator

muscle, raises the forehead and eyebrows medially and can elevate the eyelid as high as 5 mm at maximal action.<sup>25</sup> Contraction of the frontalis produces horizontal forehead rhytides. The depressor muscles—the procerus and corrugator supercilii—move the eyebrow medially and downward and contribute to the formation of glabellar rhytides. The orbicularis oculi—the sphincter muscle of the eyelids—is a wide, concentric band of muscle responsible for blinking, eyelid closure, and the production of lateral canthal and lower eyelid rhytides. The orbicularis oculi also contributes to glabellar frown lines and helps lower the brow as part of a protective mechanism of the eye.

**Fig. 12.16.1** Vascular Structures of the Upper Face.

## THE BROW AND TEMPLE

The forehead, glabella, and temples are often assessed as one aesthetic unit and treated simultaneously with a combined approach using BoNTA for muscle control and soft-tissue fillers to improve temporal hollowing and the contours of the forehead.<sup>26</sup>

### Rhytides in the Upper Face

Hyperkinetic musculature contributes to the emergence of rhytides in the forehead, glabellar region, lateral canthal area (“crow’s feet”), and infra-orbital region. Targeting overactive muscles with appropriate doses of BoNTA reduces mimetic musculature and softens the appearance of lines and wrinkles (Figs. 12.16.2 and 12.16.3). Some evidence exists that regular, repeated treatments over many years not only prevent the formation of new wrinkles but may reduce the appearance of established rhytides.<sup>14–16,18</sup> Current consensus guidelines recommend a panfacial approach to the treatment of facial rhytides using lower minimum doses and number of injection points than previously recommended (Fig. 12.16.4, Table 12.16.1).<sup>6</sup> Growing evidence supports simultaneous treatment of multiple areas for significant improvements in clinical outcomes and patient satisfaction. One study of 917 subjects revealed greater benefit when lateral canthal and glabellar lines were treated simultaneously than when crow’s feet were treated alone.<sup>27</sup>

### Shaping the Brow

Adept use of neuromodulators can lift and shape the brow as required, particularly for women, who often desire a higher, more arched eyebrow.<sup>28</sup> Indeed, the position of the eyebrows is critical for emotional expression. Changes to the angle, height, and curve of the eyebrow, alone or in combination with other facial movements, can produce a broad range of signals

**Fig. 12.16.2** Full frown before (A) and after (B) BoNTA in the glabella of a patient from the first published report of the efficacy of botulinum neurotoxin for the treatment of glabellar rhytides.

**Fig. 12.16.3** Crow’s feet at maximum smile (A) before and (B) after injections of BoNTA.

**Fig. 12.16.4** Injection points for treatment of glabellar rhytides with BoNTA in (A) men and (B) women.

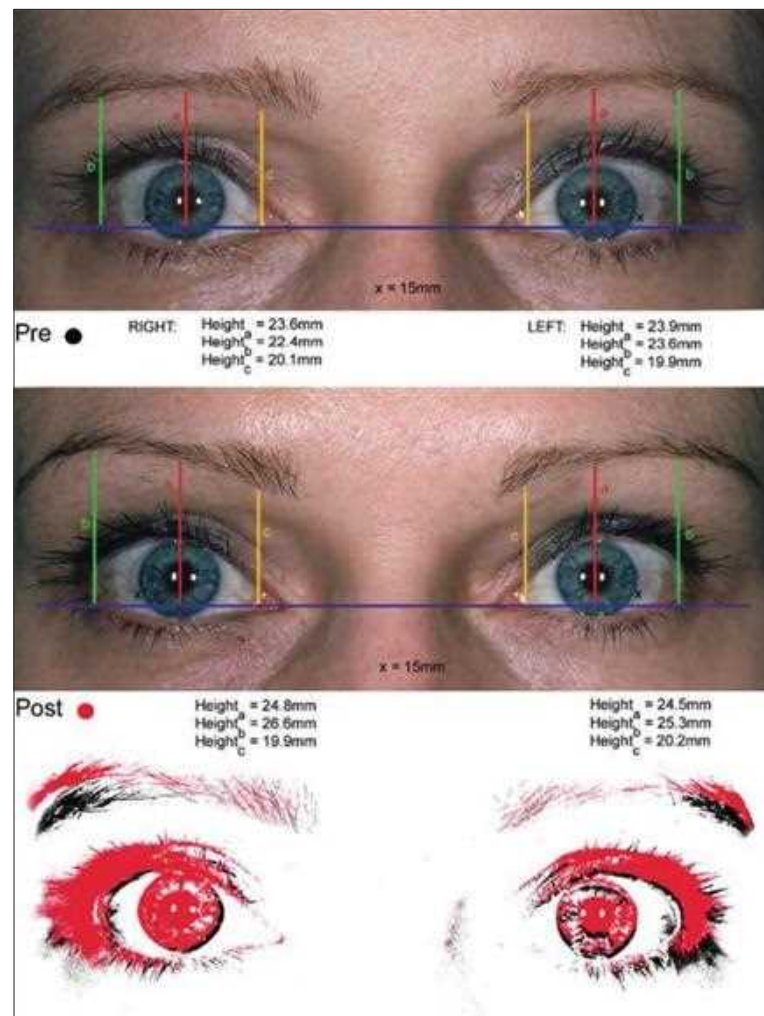

**TABLE 12.16.1** Recommendations for Periorbital Treatment With OnabotulinumtoxinA

Indication	Number of Injection Points	Total Dose
Glabellar rhytides	3–7	12–40 U
Horizontal forehead lines	4–8	8–25 U
Lateral canthal rhytides	1–5 per side	6–15 U per side
Infraorbital rhytides	1–3 per side	0.5–2 U per side

Adapted from Sundaram H, Signorini M, Liew S, et al. Global Aesthetics Consensus: botulinum toxin type A—evidence-based review, emerging concepts, and consensus recommendations for aesthetic use, including updates on complications. *Plast Reconstr Surg* 2016;137:518e–529e.

across the spectrum of human emotion that radically alter the expression of the face and serve as nonverbal forms of communication to convey emotion.<sup>29</sup>

Following the first published report of glabellar frown lines treated with BoNTA in 1992, clinicians began to observe subtle brow elevation after treatment of the brow depressors.<sup>30</sup> Central injections of 20–40 U of onabotulinumtoxinA into the glabella alone (with the most lateral injection at the midpupillary line) produced a dramatic lateral eyebrow elevation, followed by an entire chemical brow lift, due to diffusion of the toxin into the inferomedial frontalis, causing a compensatory increase in the resting tone of the lateral remainder of this muscle (Fig. 12.16.5).<sup>31</sup> Understanding that the shape and height of the eyebrow are determined by the opposing activity of the frontalis muscle and the brow depressors allows the clinician to manipulate eyebrow position at will to improve aesthetic appearance and correct asymmetry.

**Fig. 12.16.5** Eyebrow Lift After Bonta.

## Temple and Forehead Contouring

Facial recontouring aims to restore facial proportion that may or may not have been present naturally. The forehead and temple area are particularly amenable to contouring with fillers. Over time, skin laxity and relative muscle atrophy create temporal wasting and the development of concavity between the frontal eminence of the forehead and the supraciliary arches.

When injecting in the temple, there are three main anatomical structures to avoid: the superficial temporal artery and frontal branch of the facial nerve, which are located in the subcutaneous fat, and the median temporal vein, which lies 1.5–2 cm above the superficial border of the zygoma and deep in the temporalis muscle.<sup>32</sup> Subsequent massage of the area will evenly distribute the filler material.

To augment the forehead, deep injections are placed laterally at least 1 cm from the supraorbital foramen and directed posterior to the frontalis muscle in the preperiosteal plane using a low to medium viscosity filler with some lift capability, taking care to avoid the danger zones with the adjacent neurovascular bundles. The use of small aliquots of no more than 0.4 mL each rather than bolus and restricting tissue molding to the immediate postinjection period are recommended to reduce or eliminate the risk of migration.<sup>33</sup>

Alternately, a subgaleal injection technique has been developed for three-dimensional forehead augmentation in which 0.5 cc HA is diluted with 2% lidocaine with 1/200 000 epinephrine and preserved bacteriostatic saline to reduce viscosity and injected at three injection points in the forehead: centrally above the nasal bridge between the supratrochlear vessels and at the tail of each eyebrow between the temporal and supraorbital vessels (Fig. 12.16.6).<sup>34</sup> The needle or cannula is inserted into the subgaleal space as the skin is lifted away from the periosteum in the glabella and lateral brow before injection (Fig. 12.16.7). This technique results in a soft, rounded forehead, a reduction in etched forehead rhytides, and mild brow elevation without loss of expressivity (Figs. 12.16.8 and 12.16.9).

Superficial injections (high subcutaneous or intradermal) may be used for glabellar rhytides and horizontal forehead lines.<sup>33,35</sup> However, the forehead is an unforgiving area, with too much or inappropriate placement

of product leading to contour irregularities or the Tyndall effect, in which superficial implantation of certain formulations of HA imparts a bluish discoloration. Low-viscosity formulations are recommended for intradermal injection and subgaleal volumizing.<sup>34</sup>

## THE EYE

The eye speaks volumes about health, youth, and sense of attractiveness. Orbits that are large, round, and hollow are associated with age.<sup>36</sup>

**Fig. 12.16.6** Three Injection Portals Used for Three-Dimensional Forehead Reflation. (Reprinted with permission from Carruthers J, Carruthers A. Three-dimensional forehead reflation. *Dermatol Surg* 2015;41[Suppl 1]:S321–4.)

Manipulating the shape and appearance of the eye with injectables—BoNTA or soft-tissue fillers—is an evolving art, with techniques that are sometimes difficult to describe and results that cannot always be predicted.

## Widening the Palpebral Aperture

The palpebral aperture can be widened by subcutaneous injections of BoNTA into the lower lid with concomitant treatment of crow's feet.<sup>37</sup> Small doses (2–4 U onabotulinumtoxinA) placed subdermally in the lower eyelid in the midpupillary line, 3 mm below the ciliary margin, will simultaneously increase the vertical palpebral aperture by 2–3 mm at rest and full smile, respectively, lending to a more rounded appearance to the lower eyelid (Fig. 12.16.10).

## Lid Ptosis, Malposition, and Asymmetry

BoNTA is an effective treatment for the temporary management of mild-to-moderate upper lid ptosis, malposition, and eyelid-fissure asymmetry.<sup>38</sup> In the upper lid, low doses injected subdermally into the extreme medial and lateral aspects of the pretarsal region of the orbicularis just above the lash line allow unopposed activity of the levator palpebrae and Müller's muscle and a return to symmetry. Likewise, malposition and asymmetry in the lower eyelid (such as retraction, ectropion, and entropion) can be restored by weakening the lower lid elevators on the side opposite the lower lid retractions by two injections of BoNTA: one placed at the extreme lateral aspect of the lower eyelid and the other at the mid aspect of the lower eyelid pretarsal region, located approximately midpupil, inducing a similar retracted effect. Doses range from 0.5–1.5 U of onabotulinumtoxinA per injection site, with higher doses reserved for cases of lower eyelid hypertrophy and severe ptosis or when changing the position of the lower eye.

## Orbital Augmentation

Using fillers around the orbit is more complicated. The periorbital region is not an area for novice injectors. There are no hard and fast rules; only experience can predict individual aesthetic outcomes. The goal of treatment is not necessarily to make the orbit fuller or fill a hollow but

**Fig. 12.16.7** (A) Pinching up the lateral brow and (B) glabellar skin to enter the subgaleal plane. (C) Massaging the subgaleal HA to smoothness. (Reprinted with permission from Carruthers J, Carruthers A. Three-dimensional forehead reflation. *Dermatol Surg* 2015;41[Suppl 1]:S321–4.)

**Fig. 12.16.8** (A) Before and (B) after three-dimensional forehead reflation with HA. (Reprinted with permission from Carruthers J, Carruthers A. Three-dimensional forehead reflation. *Dermatol Surg* 2015;41[Suppl 1]:S321–4.)

**Fig. 12.16.9** (A) Before and (B) after three-dimensional forehead reflation with HA and 30 U onabotulinumtoxinA. (Reprinted with permission from Carruthers J, Carruthers A. Three-dimensional forehead reflation. *Dermatol Surg* 2015;41[Suppl 1]:S321–4.)

**Fig. 12.16.10** (A) Before and (B) after BoNTA to increase the width of the palpebral aperture.

to improve the appearance of the periorbital region as a whole. Not all eyes will respond favorably to the addition of volume, but a tiny amount of filler placed in appropriately selected patients can make a noticeable difference.

Injections placed deep to the orbicularis muscle but superficial to the bone keeps the needle or cannula away from the globe and the large immobile periosteal arteries. Trial injection of local anesthetic across the upper lid is a near-accurate demonstration of the intended effect of the subsequent reflation of the brow and upper lid and can be followed by actual injection of HA if the result is aesthetically pleasing.<sup>36</sup> Some injectors prefer to begin laterally and place three fanning fills—high, middle, and low—across the brow using tiny amounts of filler (typically 0.5 mL per side); avoiding overfill is difficult to do well and easily but is critical to success. Lateral and central injections typically do not drop below the border of the orbital bone.

### Infraorbital Hollow

The infraorbital hollow (IOH), or “tear trough,” refers to the U-shaped or curvilinear depression under the eyes that may be accentuated as part of the aging process. With thin skin overlying bone and little to no subcutaneous fat or muscle in this region, the IOH can be an unforgiving region and challenging to treat with injectable agents. The orbicularis oculi muscle has direct bony attachment for approximately one-third of the orbital rim length, from the nasal bone to the medial limbus. Injections seem to work best in patients with thick and smooth skin and a well-defined tear trough,

without excessively protruding eyelid fat or excess eyelid skin, and HA is the agent of choice for many injectors. Some patients have genetically determined pigmentation that may look like a tear trough but without an indentation that can be filled. Pigmented dark lower eyelid circles cannot be improved by fillers and can, in fact, be worsened by treatment.

Optimal revolumization recognizes that other areas of the face may influence the appearance of the lower eye.<sup>39</sup> A deflated medial cheek, for example, will look unnatural without concurrent augmentation, particularly on animation. Ideally, periorbital volume augmentation should be performed in conjunction with rejuvenation of the midface and sometimes to the entire face to preserve harmony and restore aesthetic proportion.

Anatomical areas of concern include the prominent infratrochlear vessels and the infraorbital nerve. Small amounts of filler—no more than 1 mL in total for both sides—are placed along the orbital rim deep in the suborbicularis plane at the suprapariosteal level except in the medial aspect of the orbicularis oculi, which attaches to bone and requires direct injection. A variety of injection techniques have been described in the literature, although linear threading and serial puncture are the most commonly used techniques.<sup>39</sup>

### ADJUNCTIVE THERAPIES

Other therapies used frequently in the periocular region include monopolar radiofrequency (MRF) to tighten the skin and reduce the appearance of fine lines,<sup>40</sup> and bimatoprost, a prostaglandin analog that was discovered serendipitously to lengthen and darken the eyelashes.<sup>41</sup>

MRF is noninvasive technology widely used in cosmetic dermatology to treat the clinical signs of photodamage—skin laxity, fine lines, and rhytides—without significant recovery time or complications.<sup>42</sup> RF devices use an electrical current rather than a light source to deliver uniform heat to the deep dermis and underlying tissue at a controlled depth with concomitant surface skin cooling. RF generates heat based on the tissue's natural resistance to the movement of electrons in the deeper dermis and underlying tissue, leading to immediate collagen contraction and a delayed wound healing response, with new collagen formation 2–6 months post treatment.<sup>42</sup> In the periorbital region, RF produces objective and subjective reductions in wrinkles and fine lines and measurable changes in brow position.<sup>43</sup>

In December 2008, bimatoprost ophthalmic solution 0.03% was approved for the treatment of hypotrichosis of the eyelashes in the United States.<sup>41</sup> Originally used in glaucoma to reduce high intraocular pressure, bimatoprost increases the length, fullness, and darkness of the eyelashes. Current evidence suggests topical application of bimatoprost to the upper lid margin once daily is a safe and effective method of enhancing the appearance of the eyelashes with a significant level of patient satisfaction.<sup>41,44,45</sup>

## PRECAUTIONS

Most side effects and complications associated with BoNTA and fillers are minor and transient. Some precautions must be taken with respect to injections in the upper face to avoid serious and potentially devastating complications.

### Chlorhexidine

A cornerstone of modern aesthetic practice is effective antiseptic before any minimally invasive procedure to reduce infection. Chlorhexidine gluconate-based antiseptics are among the most effective and widely used products for surgical and dermatological procedures. However, a recent investigative review of chlorhexidine in the face and neck unearthed abundant case reports clearly demonstrating the potential for permanent visual damage in the form of corneal injury when chlorhexidine inadvertently comes in contact with the eye.<sup>46</sup> Although povidone–iodine has been suggested as a suitable alternative, more evidence on chloroxenol-based skin antiseptics and other convenient, effective formulations is needed to make informed decisions about the choice of antiseptic for use on the face and neck.

### Vascular Compromise

The most feared complications in aesthetic ophthalmology and dermatology fall under the umbrella of vascular compromise, which is believed to be caused by compression of a vessel or direct injection of filler material into the vasculature.<sup>47</sup>

Vessel obstruction or compression causes impending tissue necrosis and possible scarring and typically occurs immediately after injection, although delayed presentation has been reported.<sup>48</sup> Vascular compromise is evident by painless blanching that may be subtle and initially unrecognized; untreated, this progresses to a painful, violaceous reticulated patch, ulceration, and subsequent scar formation. Proper technique—using caution in high-risk areas, choosing low volumes of reversible HA fillers over multiple treatment sessions, using small-gauge needles or blunt canulas, and injecting slowly, with low pressure—may reduce the risk.

Inadvertent injection into the terminal or proximal branches of the ophthalmic artery results in often-irreversible blindness and possible

concomitant stroke. Blindness occurs abruptly and painfully.<sup>47</sup> Prevention is critical but not always possible due to anatomical variation; vascular compromise does occur despite extensive knowledge of vasculature and relevant injector experience. Extreme caution and the use of HA formulations are advised when injecting fillers into high-risk areas. Blindness is most often associated with injections in the glabella,<sup>49</sup> a watershed of small vessels, with minimal collateral circulation, requiring only small amounts of filler material to cause obstruction of blood flow. The central retinal artery is the final branch of the ophthalmic artery; proximal branches include the supratrochlear, supraorbital, and dorsal nasal artery, which partly supplies the dorsum of the nose. The angular artery—the terminal branch of the facial artery—ascends along the nasolabial fold and is particularly susceptible to vascular injury.<sup>47</sup> Treatment protocols advocate early recognition of retinal artery occlusion and timely retrobulbar injection of large amounts of hyaluronidase to decomplex intravascular HA for the best chance of preventing otherwise almost certain partial or complete loss of vision.<sup>47</sup>

## CONCLUSION

Modern rejuvenation of the periorbital region comprises a global, panfacial approach using a combination of neuromodulators and soft-tissue fillers to restore balance and youthful contours to the face. With its long history of use in ophthalmology, BoNTA reduces mimetic musculature contributing to dynamic and static rhytides and can be used to lift the eyebrows and widen the eyes. HA fills deeper lines and folds and targets the loss of subcutaneous support, shaping the orbit and recontouring the forehead and temples. However, certain areas of the upper face pose a greater risk for sometimes devastating complications. Proper injection technique and recognition of risk factors may reduce the incidence of vascular compromise and promote safe and successful outcomes.
